Another foliage characteristic that distinguishes most conifers from other evergreen vegetation is the duration that leaves remain functional. Conifers generally hold some foliage for 3–5 years, although a few species maintain functional leaves for 30–40 years (Landsberg and Gower, 1997). The fact that temperate evergreen conifers can maintain dense, needle-leaf canopies, composed of multiple-age classes of foliage, affects many ecosystem processes including the capture of water, nutrients, and pollutants from the air, and the rates of decomposition, nutrient release, and soil organic matter accumulation.

Anatomically, long-lived foliage is characterized by an epidermis covered with a thick waxy cuticle, above one or more layers of compactly arranged, thick-walled cells, which in turn surround a structurally reinforced vascular system. The result is that nutrient concentrations in conifer needles may be only half those in deciduous hardwood leaves of equivalent mass. Lower nutrient concentrations in individual leaves translate into lower demand, yet long-lived foliage provides a greater store of nutrients available for transfer during peak growth periods than is available in deciduous hardwoods.

In addition, in environments where mineral weathering rates are slow and nutrient availability limited, evergreen conifers can take up nutrients from the soil as long as conditions remain above freezing. Photosynthesis can also continue under these conditions. As a result of nutrient uptake and photosynthesis during the dormant season, stored reserves (starch, sugars, amino acids) are available to activate symbiotic fungi on tree roots that efficiently scavenge nutrients. In contrast, deciduous trees, which also have symbiotic root fungi, are restricted to taking up nutrients when foliage is present.

The evolutionary advantages that conifers have on infertile soils can place them at a disadvantage on more fertile sites. On infertile soils, most available nitrogen (N) is in the form of ammonium (NH_4^{+1}), which conifers take up selectively in preference to nitrate–nitrogen (NO_3^{-1}). As nitrate–nitrogen becomes more available, conifers are disadvantaged in competition with hardwoods (Smirnoff and Stewart, 1985).

ECOSYSTEM RESPONSES OF TEMPERATE CONIFEROUS FORESTS

Decomposition

Leaf litter, wood, and root materials produced by evergreen conifers usually contain twice the amount of carbon (C) in relation to nitrogen found in corresponding materials produced by deciduous angiosperms. As a result, the decomposition of coniferous litter is usually 3–4 times slower than hardwood litter, leading to a greater accumulation of forest floor litter under conifers (Figure 1).

With time, as litter decays, soils under coniferous forests maintain high C–N ratios and serve as storage sites for amounts of carbon that far exceed above-ground biomass, and have turnover times of centuries and millennia. This property of coniferous forest ecosystems, combined with their potential rapid growth, makes them an attractive vegetation type to manage for the sequestration of large amounts of atmospheric carbon dioxide (CO_2).

Hydrology

The potential of evergreen coniferous forests to maintain dense, well ventilated canopies throughout the year significantly increases the annual water vapor transfer from

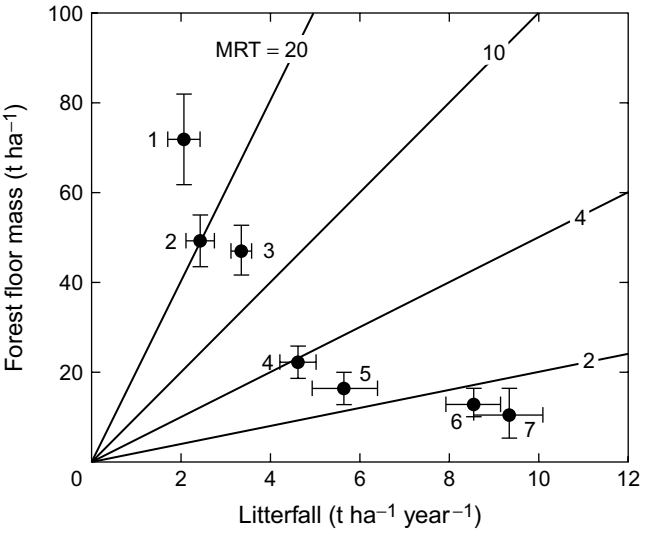

Figure 1 Average forest oor mass plotted against litter-fall for (1) boreal needle-leaved evergreens, (2) boreal broad-leaved deciduous, (3) temperate needle-leaved evergreen, (4) temperate broad-leaved evergreen, (5) temperate broad-leaved deciduous, (6) tropical broad-leaved evergreen, and (7) tropical broad-leaved deciduous trees. Assuming the forest oor is at steady state, the average mean residence time (MRT, years) can be calculated as forest oor mass/litterfall mass. The lines indicate that forest oor litter of temperate needle-leaved evergreens take about 15 years to turnover whereas other temperate hardwoods turnover in <4 years. (Reproduced from Landsberg and Gower, 1997)

their canopies, relative to deciduous forests. As a result, evergreen coniferous forests reduce stream flow by an average of 15–25% in comparison to deciduous hardwoods in similar environments (Waring and Schlesinger, 1985). The dense, finely dissected canopies of evergreen conifers also have the propensity to condense water (and pollutants) from clouds, leading to fog drip, which can increase the effective precipitation at high elevations substantially in windy environments (Harr, 1982).

Water stored in the sapwood of conifer trees can serve as a temporary buffer against drought. During the day, this reservoir may contribute up to a third of the water transpired, with refilling taking place during the night. In general, the ratio of sapwood mass to leaf area increases in conifers with harshness of the environment (Waring and Running, 1998); the total volume of sapwood determines the reservoir of water. Thus, a 50 m tall Douglas fir forest with about a quarter of the stem composed of sapwood may hold 30 mm of stored water whereas a 15 m tall pine forest, with stems composed largely of sapwood, can hold 20 mm of stored water (Waring and Running, 1978; Waring *et al.*, 1979). In a few species, such as redwood, the voluminous heartwood also plays an important role as a reservoir.

RESPONSE OF TEMPERATE CONIFEROUS FORESTS TO AIR POLLUTION

In clean environments, nitrogen deposition is usually $<5\,kg\,ha^{-1}\ year^{-1}$ whereas in heavily polluted areas, nitrogen additions exceed $50-70\,kg\,ha^{-1}\ year^{-1}$. Much of this excess nitrogen ends up as nitrate, which is easily leached in soil solution. The negatively charged nitrate ions extract calcium, magnesium, and other positively charged nutrient from soil cation (+) exchange sites. Because weathering rates are slow, the lost nutrients are often replaced with positively charged acid radicals (H^{+1}) and toxic forms of aluminum (Al^{+3}). As a result, a nutrient imbalances may arise where the availability of nitrogen is in excess to that of other elements, creating conditions where plants become more nutritious, and less resistant to attack from a variety of organisms (Waring and Running, 1998).

In areas where hydrocarbons released by the combustion of fossil fuels interact with sunlight, ozone ($O_3{}^{-3}$) is formed. Ozone is a highly reactive oxidizing agent that diffuses through stomatal pores on leaf surfaces when they are open and injures the photosynthetic machinery inside. Over a single growing season, conifer foliage suffers less damage than deciduous hardwoods because gas exchange rates through stomata are only about half those of deciduous hardwoods for an equivalent surface area (Reich and Amundson, 1985). With continued exposure, however, older foliage on conifers sustains accumulated damage and is shed prematurely (McLaughlin, 1985), leading to reduction in tree vigor and a greater likelihood of disease and insect outbreaks (Waring and Running, 1998).

RESPONSE OF TEMPERATE CONIFEROUS FORESTS TO CLIMATIC CHANGE AND INCREASING ATMOSPHERIC CO_2

We might expect temperate coniferous forests to be favored over deciduous hardwoods if climatic conditions during the dormant season become more favorable and those during the growing season less so. Thus, if minimum temperatures rise during the winter, the constraints exerted by subfreezing and suboptimal temperatures on photosynthesis will be reduced (Runyon *et al.*, 1994; Landsberg and Waring, 1997). The relative importance of warmer conditions during the winter can be assessed by considering the seasonal shifts in potential radiation available at different latitudes, aspects, and slopes to evergreen conifers (Running *et al.*, 1987; Waring and Running, 1998). If warming is combined with more frequent storms, without necessarily any increase in total precipitation, the associated increase in cloud cover may substantially reduce solar energy available to melt snow or drive photosynthesis.

On the other hand, if climatic warming extends throughout the year, the growing season will be lengthened. A higher frequency of storms in this case could moderate summer temperatures by allowing vegetation to maintain transpiration at near maximum rates and reduce the fraction of energy going into heating the air (Figure 2). More frequent wetting of surface litter and soil would also foster more rapid decomposition and release of nutrients, while reducing the likelihood of forest fires. This climatic scenario would favor replacement of conifers by hardwoods.

To factor in the response of vegetation to rising atmospheric CO_2 concentrations is more of a challenge. In general, increases in CO_2 should result in elevated rates of photosynthesis because carbon dioxide is a limiting resource for all tree species. Moreover, a rise in CO_2 should reduce photorespiration and increase the efficiency of photosynthesis, particularly if conditions become warmer. Because stomatal adjustments in most tree species maintain CO_2 concentrations within their leaves at about 75% of the value in ambient air, we might conclude that rising atmospheric CO_2 will result in a net reduction in transpiration per unit leaf area, and thus increased carbon gain per unit of water lost. This may be generally true for many hardwood species, but there is less evidence that conifer stomata respond similarly (Norby *et al.*, 1999). In fact, in one field experiment where ambient CO_2 levels were artificially elevated for more than two years, no shift in pine stomata behavior was recorded (Ellsworth, 1999).

If net photosynthesis were to increase significantly, canopy leaf area index would reach a higher value, assuming sufficient nutrients were available. An increase in leaf

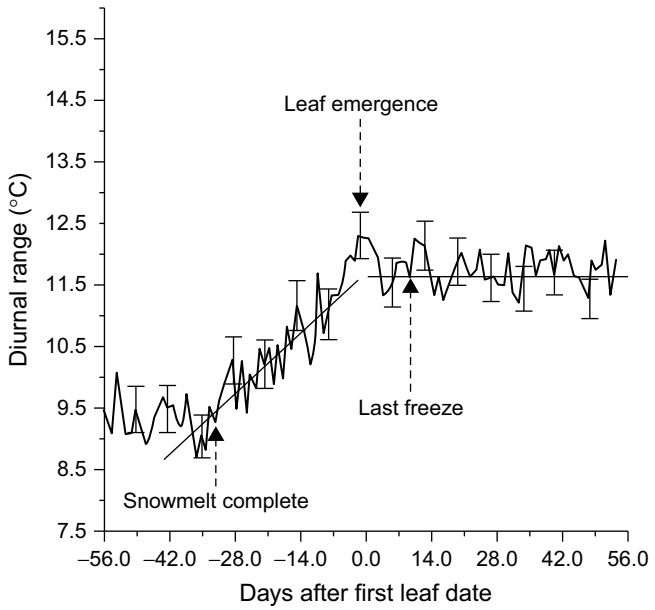

Figure 2 Average daily surface temperature amplitude (maximum- minimum), measured before and after spring leaf emergence of local vegetation for 12 sites across the north-central United States. The rapidly warming spring temperatures generate progressively larger temperature amplitudes during the 2- 3 week period prior to lea ng out; the amplitude is dampened, however, by leaf emergence as partitioning of incoming solar radiation is shifted as a result of cooling by rapidly transpiring vegetation. (Reproduced from Schwartz and Karl, 1990; Waring and Running, 1998)

area would affect the water balance by increasing canopy interception, evaporation, and transpiration under a stable climate. On the other hand, if climatic conditions were to warm without a corresponding increase in precipitation, drought could reduce photosynthesis, growth, and canopy leaf area.

In summary, although changing patterns of climate and atmospheric CO_2 concentration together are likely to have subtle effects on tissue biochemistry and the allocation of resources, forest growth and composition could be dramatically altered as a consequence of disturbance from outbreaks of fire, diseases, and insects.

FOREST MANAGEMENT OPTIONS

With increasing demand for forest products, and increasing appreciation of other values derived from forests, there is considerable controversy and concern over how forests, on both public and private lands, are to be managed. Temperate coniferous forests have tremendous value to human societies, so there is justified concern about their management. Ancient coniferous forests have long been appreciated by many cultures as places of beauty, often with religious significance. Many groves have been designated as sacred and others set aside as natural wonders to be preserved in parks. The value of forests for maintaining clear running streams and high quality drinking water has also been long appreciated. Recently, modifying the structural characteristics of young coniferous forests to create properties more typical of mature stands has gained acceptance as a means of creating more favorable habitat for rare and endangered species commonly associated with extremely old forests. At the same time, ways of increasing the amount of carbon stored in biomass and soils are being developed. These carbon-sequestering techniques affect site preparation and harvests as well as the design, use, and recycling of forest products.

It is clear that young plantations will play an increasing role in providing lumber and fiber: whether these plantations replace native species or reclaim marginal farmland, however, will make a difference in the extent that plant and animal biodiversities are affected. Similarly, the fraction of the landscape occupied by plantations will alter the likelihood of fire, water runoff, and the potential for outbreaks of insects and diseases.

The challenge associated with more active management for wood, water, biodiversity and carbon storage, is the need to anticipate the extent to which disturbances may occur across broad landscape and ownership patterns. The introductions of exotic organisms into native forests is a particular concern because exotic insects and pathogens can result in replacement of native trees and open the environment to invasion by noxious weeds and other organisms.

General models that employ computer and satellite technology to compare projected changes with those that can be observed across broad landscapes and regions can provide a valuable aid to decision making. Remote sensing technology by itself permits us to monitor the state of the Earth's vegetation and the extent of change in vegetative cover over the last three to four decades.

Temperate Deciduous Forests

Peter B Reich and Lee Frelich
University of Minnesota, St. Paul, MN, USA

Temperate deciduous forests are among the major biomes on earth. They are also among the biomes that have been most heavily impacted by global change factors. Although there is the perception that the greatest concern should be held for tropical rain forests, temperate deciduous forests have a smaller fraction of original vegetation remaining than boreal or tropical forests, and also have been more severely impacted by land use change and air pollution. Temperate deciduous forests are most common in Europe, eastern North America, Japan and China, and in all these regions humans have used them heavily as a resource. Logging, grazing, conversion to agriculture, fire suppression and manipulation of wildlife populations, have caused massive alterations of forest composition, structure and diversity. Temperate biomes in Europe and North America bore the brunt of the industrial revolution, providing wood for fuel, building materials, and raw material in industrial processing. Boreal biomes have been spared widespread permanent conversion in vegetation type due to their inappropriateness for intensive agriculture. Conversion from native vegetation to agricultural landcovers has become widespread in the tropics only late in the 20th century. Thus, temperate forests have experienced more severe impacts over broader areas than any other large forest biome (Williams, 1989).

Additionally, because they are present in some of the most heavily populated and industrialized regions on earth, temperate deciduous forests have also been subject to biological invasions and to elevated levels of air pollution, including ozone, sulfur dioxide (i.e., acid deposition) and nitrogen deposition. Nonetheless, the land covered by temperate deciduous forests (as opposed to land once converted to agriculture) generally increased late in the 20th century. In this essay, we will describe the extent and characteristics of temperate deciduous forests, and the major global change agents that impact them.

NATURE AND EXTENT OF TEMPERATE DECIDUOUS FORESTS

Temperate deciduous forests occupy a central position among the world's biomes, occurring in regions of intermediate temperature, precipitation and latitude. They are bracketed geographically by biomes that are more extreme in climate, productivity and diversity: boreal forest and tundra to the colder high latitudes; temperate coniferous forests

and grasslands toward the drier climate zones; and tropical forests in warmer regions (Reich and Bolstad, 2001). Forest vegetation is classified by broad climate zones (tropical, temperate, boreal) and by leaf form and habit (broad versus needle-leafed forest, evergreen versus deciduous). Temperate forests are considered one of the five dominant forest types, along with boreal forest, temperate mixed or coniferous forests, subtropical/tropical wet forests, and subtropical/tropical dry forests. Generally, a forest is considered temperate if it is found in a climate with a warm summer and a markedly cool or cold winter. Typically, temperate forests are found between 3 and 18 °C mean annual temperature, with midwinter mean monthly temperatures generally below 8 °C and midsummer mean monthly temperatures generally above 18 °C.

Temperate forests occupy much of North America, Europe, Asia, Australia, New Zealand, and a small part of South America, but those in the southern hemisphere are almost exclusively evergreen, so temperate deciduous forests are generally restricted to mid-latitudinal belts in the Northern Hemisphere. Although needle-leafed deciduous forests occur, the most common of these are Larix-dominated and typically a component of boreal forests and these will be largely ignored in this essay. Thus, we will focus on broad-leaved forests.

Broad-leafed deciduous forests typically occupy colder and/or moister parts of the temperate zone than broad-leafed evergreen forests, which span the ecotones between warm temperate, subtropical, and Mediterranean biomes. For instance, in Japan, moving from north to south within a continuously moist climate, native forests are dominated by mixed conifer–hardwood forests in the cold temperate north, by broad-leafed hardwoods in the central region, and in the warm temperate south, by mixed deciduous–evergreen or evergreen broad-leafed forests.

MAJOR GLOBAL CHANGE ELEMENTS, MECHANISMS OF IMPACT, AND MAGNITUDE OF EFFECTS

There are a number of different global change factors that collectively influence temperate deciduous forests of the world. These include land use history, current land management, climate change, fire suppression, changes in atmospheric chemistry, and invasions of exotic species. These human impacts on temperate forests have been both direct and indirect. Direct impacts include site conversion to other land covers and land uses, including inadvertent effects on the native species composition. Indirect impacts include the introduction or elimination of herbivorous or competing species, fire suppression and attendant changes in disturbance regimes, atmospheric pollution, particularly carbon dioxide (CO_2), ozone, sulfur, and nitrogen compounds, changes in the age structure of forest through cutting patterns and practices, and changes in stand age demographics on longer time scales related to historical changes in local, national, and global economies. Although their effects tend to interact, for simplicity we will discuss each in turn.

Land Use History

Almost all temperate deciduous forests have been severely impacted by human use. In Europe and North America, less than 1% of all temperate deciduous forests remain in undisturbed state, free of logging, grazing, deforestation or other intensive use. The largest direct impacts on temperate deciduous forests stem from conversion to other land uses. Pre-industrial forest extent is unknown, but conversion to other landcovers has been profound. Native forests have been all but eliminated in some countries, such as Ireland and Britain. In general, roughly half the original temperate deciduous forestland has been converted to other uses, primarily agriculture. Thus, forest conversion to agriculture has been of critical importance. In Europe, massive deforestation occurred centuries ago. In eastern North America, deforestation migrated westward with agricultural settlement from the 1600s to the mid 1800s. For instance, lands originally almost entirely forested, such as Vermont, were more than 80% deforested and converted to agriculture in the 19th century. However, many temperate zone economies have shifted from rural, agricultural to urban manufacturing and technologically driven economies. This has led to large-scale agricultural abandonment and the reversion of agricultural lands back to forests. Recent studies indicate an increase in forest area and volumes in both North America and Europe (Kauppi *et al.*, 1992; Houghton, 1995).

Land Management and Fire Suppression

Although fire was not historically as severe a disturbance in temperate deciduous forests as in boreal or temperate coniferous forests, it nonetheless played an important historical role (Pyne, 1982). In eastern North America, Native American burning and lightning resulted in relatively frequent fire in the temperate deciduous forests. This was important to drier regions such as near the prairie–forest border. Forest fire had a tremendous impact on the composition and age structure of the forest, since certain species have adaptations such as thick bark, ability to sprout, and rapid post-fire colonization that enable them to thrive under such conditions (Reich *et al.*, 1990; Abrams, 1992; Kruger and Reich, 1997; Peterson and Reich, 2001).

Fire frequency regulated the balance between late successional species such as sugar maple, beech, and linden and shade-intolerant early successional species of oak and aspen. Oak and aspen were most abundant along the prairie

forest border and areas with sandy soil where fires were most frequent (Grimm, 1984; Abrams, 1992).

With increasing development following European settlement and expansion, fires in temperate deciduous forests became much less frequent. This was due to cessation of intentional burning, direct suppression of fires, and land use changes that disrupted the contiguity of burnable vegetation across the landscape. Hence, temperate deciduous forests have gradually become increasingly dominated by shade-tolerant species such as maple, beech, ash, and linden, with decreased abundance of oaks (Crow, 1988; Abrams, 1998). In the absence of fire, oaks do not establish well in either shaded understorys or sunlit openings, because they are neither shade tolerant nor fast growing (Reich *et al.*, 1990; Abrams, 1992; Kruger and Reich, 1997). Hence, a major change in temperate deciduous forests of North America has resulted from the ascendency of fire-intolerant species to a dominant position in these regions. However, oaks are expanding their range westward into the prairie–woodland region, as a consequence of fire suppression. Fire suppression has likely had similar effects in Europe and Asia, but the greater time since active fire regimes makes it more difficult to be specific about the changes that have occurred.

Along with fire management, silvicultural management has also altered the temperate deciduous forest regions of Europe and North America (Parry, 2000). In Europe, almost all native temperate deciduous forest has been extirpated and of the remaining area still forested, or again forested, the majority has been planted to monocultures or mixtures not necessarily representative of the native vegetation. Much native temperate deciduous forestland has been planted with Scots pine or Norway spruce monocultures, or deciduous mixtures dominated by Fagus. In North America, many temperate deciduous forests have been replaced by pine plantations or mixed forests, especially in the southeast. Conversely, forests dominated by pines in the northern range of temperate deciduous forests have often shifted to aspen dominance following logging.

Species Effects: Local and Invasions

Local species extirpations (e.g., *Castor canadensis*, the North American beaver) and introductions (e.g., *Lymantra dispar*, the European gypsy moth to North America) can have large aggregate impacts on species composition and nutrient and mass cycling rates. The exotic Chestnut blight and Dutch elm disease have caused the virtual disappearance of native Chestnut (*Castanea*) and American elm (*Ulmus*) from the temperate deciduous forests of North America. Uncharacteristically low and high region-wide populations of beaver and white-tailed deer, respectively, have caused shifts in the relative abundance of tree species whose populations or habitat are affected by browsing of these animal species. Although temperate deciduous forests in northeastern North America have not been invaded by a successful tree canopy dominant from overseas, the Asian species *Paulownia* is a successful invader in the southeastern US and two small trees, *Lonicera* spp and *Rhamnus cathartica*, have displaced native shrubs and prevented tree regeneration in many suburban regions of the eastern US. Moreover, the nitrogen-fixing tree, *Robinia pseudoacacia* has greatly expanded its range in eastern North America in the past several centuries. In Europe, several North American species, including white pine, black locust, and red oak, were planted and have become naturalized in the temperate deciduous forest region.

Impacts on Temperate Deciduous Forests Due to Changes in Atmospheric Chemistry

The potential indirect effects of elevated CO_2 on climate warming, and resultant consequences, are addressed elsewhere (*see* various papers in volume 1, and **Intergovernmental Panel on Climate Change (IPCC): an Historical Review**, Volume 4). Additionally, due to its role as substrate for photosynthesis, elevated atmospheric CO_2 levels may directly increase forest productivity and cause shifts in species composition (Parry, 2000). Numerous hypotheses have been proposed regarding which kinds of species will be favored under enriched CO_2 conditions, with faster-growing, less shade-tolerant species often considered potentially more responsive. However, the evidence is extremely inconclusive, leaving us with high uncertainty regarding how elevated CO_2 levels will change future forests (*see* **Nitrogen Cycle**, Volume 2; **Nitrogen Deposition on Forests**, Volume 2).

Elevated levels of nitrogen deposition and tropospheric ozone are also common in temperate deciduous forests regions and known to have significant effects on forests. Atmospheric nitrogen inputs have increased significantly over the last 30 years (Aber *et al.*, 1989), with large increases in per hectare nitrogen inputs reported, particularly in Europe (Kauppi *et al.*, 1992). Nitrogen deposition may be having substantial effects on tree production and patterns of carbon and nitrogen cycling (Townsend *et al.*, 1996; Magill *et al.*, 1997). Changes in nitrogen availability could have large impacts on species composition (toward more nitrogen-demanding taxa), litter quality and quantity, decomposer populations, and nutrient and mass cycling rates (*see also* **CO_2 Enrichment: Effects on Ecosystems**, Volume 2; **Plant Growth at Elevated CO_2**, Volume 2). Ozone is present at elevated levels during the growing season in the European, North American, and probably Asian regions of temperate deciduous forests. These pollution levels are sufficient to cause reduced productivity at leaf, tree, and stand-scales (Reich, 1987; Ollinger *et al.*, 1997). Whether ozone pollution causes shifts in forest composition is still unclear. Increases in atmospheric greenhouse gases

may also have large impacts through climatic alterations (see below).

Climate

The climate in temperate deciduous forest zones has been fairly stable for the last 1000–2000 years. The impact of warming during the 20th century has not yet manifested itself in forest change, although it is likely that direct human disturbance in temperate deciduous forests would mask any change due to climate that may have occurred.

Temperate deciduous forests are heavily impacted by wind disturbance, including tornadoes and thunderstorm downbursts in central North America and hurricanes (or typhoons) and severe extra-tropical low-pressure systems for forests near the oceans. The frequency of such stand-leveling winds is expected to increase under a warmer climate, so that fewer stands would reach old-growth stages of development. Warmer climates would also cause mixed effects due to greater drought stress and fire frequency in some regions, but fewer in other regions.

POTENTIAL TEMPERATE FOREST RESPONSES TO GLOBAL CHANGE

How will changing environmental factors (climate, CO_2, nitrogen deposition, land use) collectively affect temperate forest net primary production (NPP) and associated processes? Although it is nearly impossible to address these questions empirically at the present time (due to the lack of data), these issues may be addressed from a conceptual and quantitative modeling framework (Parry, 2000; Reich and Bolstad, 2001).

Acknowledging the shortcomings of current models, what do they suggest about temperate forest responses to global change issues such as land use change, elevated CO_2, nitrogen deposition, ozone pollution, climate and other issues? Running and Nemani (1991) modeled forest ecosystem response to various climate change factors, including a doubling of atmospheric CO_2, a 4 °C temperature rise, and 10% increased precipitation, and found predicted changes which depended on the forest type and current climatic conditions. Model simulations by Aber *et al.* (1995) suggested that neither an unrealistically large (6 °C) temperature warming, a 15% decrease in mean annual precipitation, nor a doubling of atmospheric CO_2 had substantial consistent effects on NPP of temperate forests in the northeastern US. However, the occurrence of all three changes simultaneously resulted in model predictions of increased productivity because increased water use efficiency associated with elevated atmospheric CO_2 would enable sustained higher canopy photosynthesis during the summer and an extended growing season without development of severe soil water deficits. For the same region of the northeastern US, model predictions of NPP responses to ambient ozone pollution levels that occurred from 1987 to 1992 (Ollinger *et al.*, 1997) suggested that forest productivity is currently reduced by 5–10% annually across the region.

Hudson *et al.* (1994) developed a linked terrestrial/atmospheric global carbon cycling model to investigate global carbon pools, and to aid in illuminating discrepancies in the measured global carbon balance. They report concurrence with the notion of temperate forests being largely nitrogen limited, and identify increased atmospheric nitrogen deposition, originating from fossil fuel combustion and other anthropogenic sources, as contributing to large increases in carbon immobilization in terrestrial vegetation.

Using the BIOME3 model, simulations suggest that temperate deciduous forests in Europe may substantially increase in productivity under combined global change scenarios during the next 80 years (Parry, 2000). Moreover, the optimal type shifts from the more northern mixed forest to temperate deciduous forest in roughly one-third of the European temperate zone under this simulation.

SUMMARY

Temperate deciduous forests are important to regional economies as a source of wood, they provide many regional ecological services, and they play a major role in the global carbon cycle. As illustrated above, we can characterize temperate deciduous forest changes, and are beginning to understand the collective impacts of a variety of global change factors on the processes that combine to control composition and ecosystem function in these forests. As scientists, we still face enormous challenges in understanding those complex interactions and in measuring forest patterns and processes at relevant regional to global scales. In this century, temperate forests will continue to play an expanding role as demands for fiber, ecological services (such as water supply and stream water quality, carbon storage, and others), other ecological benefits (wildlife, other biodiversity) and other human values (recreation, tourism, aesthetics, spirituality) increase with burgeoning global populations. Given that temperate deciduous forests are located in regions that are highly developed and already highly disturbed by human use, their future extent, composition, health, and productivity may well signal whether human civilization at high population density is compatible with the sustainability of ecological and economic health and productivity in any ecosystem type or biome.

Temperate Grasslands

José M Paruelo

Universidad de Buenos Aires, Buenos Aires, Argentina

Temperate grasslands have been the biome most affected by one of the main dimensions of the global change: land cover modification. The replacement of grasslands by agricultural fields have local, regional, and global consequences, including loss of soil fertility, soil erosion, reduction of biological diversity, hydrological changes, climate alteration and modification of atmospheric composition. Field and laboratory experiments are beginning to show a positive response, both in total biomass production and water use efficiency (WUE) for the dominant species of temperate grasslands to the increase of atmospheric carbon dioxide (CO_2). Simulation analyses have indicated that climate change by itself has increased net primary production in most of the grassland regions of the world and has reduced soil carbon stocks everywhere. The combined effect of climate change and elevated CO_2 has increased net primary production in all the sites studied and has reduced carbon losses by half.

Temperate grasslands are an important biome in Eurasia (Paleartic realm, 7.5×10^6 km^2), North America (Neartic realm, 2.7×10^6 km^2) and southern South America (Neotropical realm, 1.1×10^6 km^2), also occupying small areas in Africa, Australia and New Zealand. At least three physiognomic types are considered grasslands in temperate regions:

meadows, prairies, and steppes. Species of the Poaceae family are dominant or co-dominant in these physiognomic types. Grasslands occur in between forest and deserts. The boundaries among these biomes are not clear, and transitional areas develop among them; scattered trees or shrubs are then a common feature in grassland areas. The relative importance of the woody components in grassland is often the consequence of the disturbance regime.

Grasslands have played an important role in human history because the centers of origin of the most important cultivated plants (wheat, barley, peas, etc.) and livestock (goats, sheep, cattle) are located in them. Humans dramatically modified grassland areas and the sub-humid portion of this biome has been almost completely transformed by agriculture.

GENERAL CHARACTERISTICS OF TEMPERATE GRASSLANDS

Climate and Soils

Grasslands occur over a broad range of temperatures. Mean annual temperature (MAT) of grassland areas range between $-3\,^{\circ}C$ in the Mongolian and Russian steppes and $20\,^{\circ}C$ in the tallgrass prairies of Texas (USA) and the desert grasslands of Northern Mexico. A large proportion of grasslands has a continental climate, showing much larger seasonal temperature differences than areas under maritime influence. The range of mean annual precipitation (MAP) where grasslands can be found varies from 150–1500 mm.

Grasslands are not evenly distributed in the climatic space defined by the ranges of MAT and MAP presented above. Grasses are not dominant where temperatures are high and precipitation low (close to the $20\,^{\circ}C$ and the 150 mm corner of a MAT–MAP graph (see Figure 1)). At this extreme, grasslands become replaced by shrublands or deserts. At the coldest and wettest extreme, forests are the dominant biome. The distribution of grasslands in the climatic space is related to the magnitude of the water deficit. Grasslands show a ratio of mean annual precipitation and potential evapotranspiration (PET) lower than 1. The MAP/PET ratio is close to 0.3 for dry steppes and to 0.6 for sub-humid prairies (*see* **PET (Potential Evapotranspiration)**, Volume 2).

Grassland soils are among the most productive under agricultural use. High productivity derives mainly from the high content of organic matter. Mollisols is the dominant soil order in this biome.

Biotic Characteristics and their Environmental Controls

An important structural characteristic of temperate grassland is that most of the carbon is stored below ground, in soil organic matter and plant roots. This large accumulation of carbon results from low decomposition rates relative to net primary production. The total amount of soil organic carbon decreases with MAT and increases with MAP (Burke *et al.*, 1989). Fine textured soils retain more organic matter than coarse textured soils (Burke *et al.*, 1989).

Despite the dominance of just one family, Poacea, grasslands show marked differences in species composition. Over continental scales, a structural comparison of grasslands based on species composition is precluded by the differences in floras among the different biogeographical realms. Such comparison is possible, though, at the plant functional level (PFT) (*see* **Plant Functional Types**, Volume 2). Five main PFTs can be identified in grassland areas: C_3 grasses, C_4 grasses, shrubs, forbs and succulents. The first three account for most of the biomass and show a clear pattern across environmental gradients. The relative abundance of C_4 grasses increases with MAP, MAT, and the proportion of precipitation falling in summer. C_3 grasses are more abundant as MAT decreases and in areas with a high proportion of precipitation falling in winter. The relative abundance of shrubs increases in dry areas with most of the precipitation falling in winter.

Above-ground net primary production (ANPP) is a key attribute of grassland ecosystems and the main entrance of energy to the ecosystem. Characterization of the climatic controls of ANPP is essential to understanding the impact of global changes on this biome. A positive, linear relationship between ANPP and MAP has been documented for many grasslands around the world (McNaughton *et al.*, 1993). The slope of the relationship between ANPP and MAP in grassland ecosystems ranges between 0.48 and $0.64\,g\,C\,m^{-2}\,mm^{-1}$. Epstein *et al.* (1997) showed a negative relationship between ANPP and MAT when MAP was held constant. Soil texture, through its effect on soil water-holding capacity, also showed a significant relationship with ANPP (Sala *et al.*, 1988; Epstein *et al.*, 1997). Below-ground net primary production is equivalent or slightly greater than ANPP. Annual net primary production (below and above ground) may vary then, from less than $100\,g\,m^{-2}$ in a semi-arid shortgrass steppe to almost $1000\,g\,m^{-2}$ in a tallgrass prairie (Paruelo *et al.*, 1999). Compared to other biomes, grasslands' above-ground biomass is low. Shrublands may have 10 times more biomass than grasslands and evergreen forest up to 100 times more (Chapin, 1993). Differences in ANPP among biomes, however, are not so extreme as in the case of biomass (Chapin, 1993). As a consequence, the ratio ANPP/biomass is higher in grasslands than in any other biome.

McNaughton *et al.* (1993) showed that biomass and consumption of wild herbivores were positively and exponentially related to ANPP. The exponential form of these

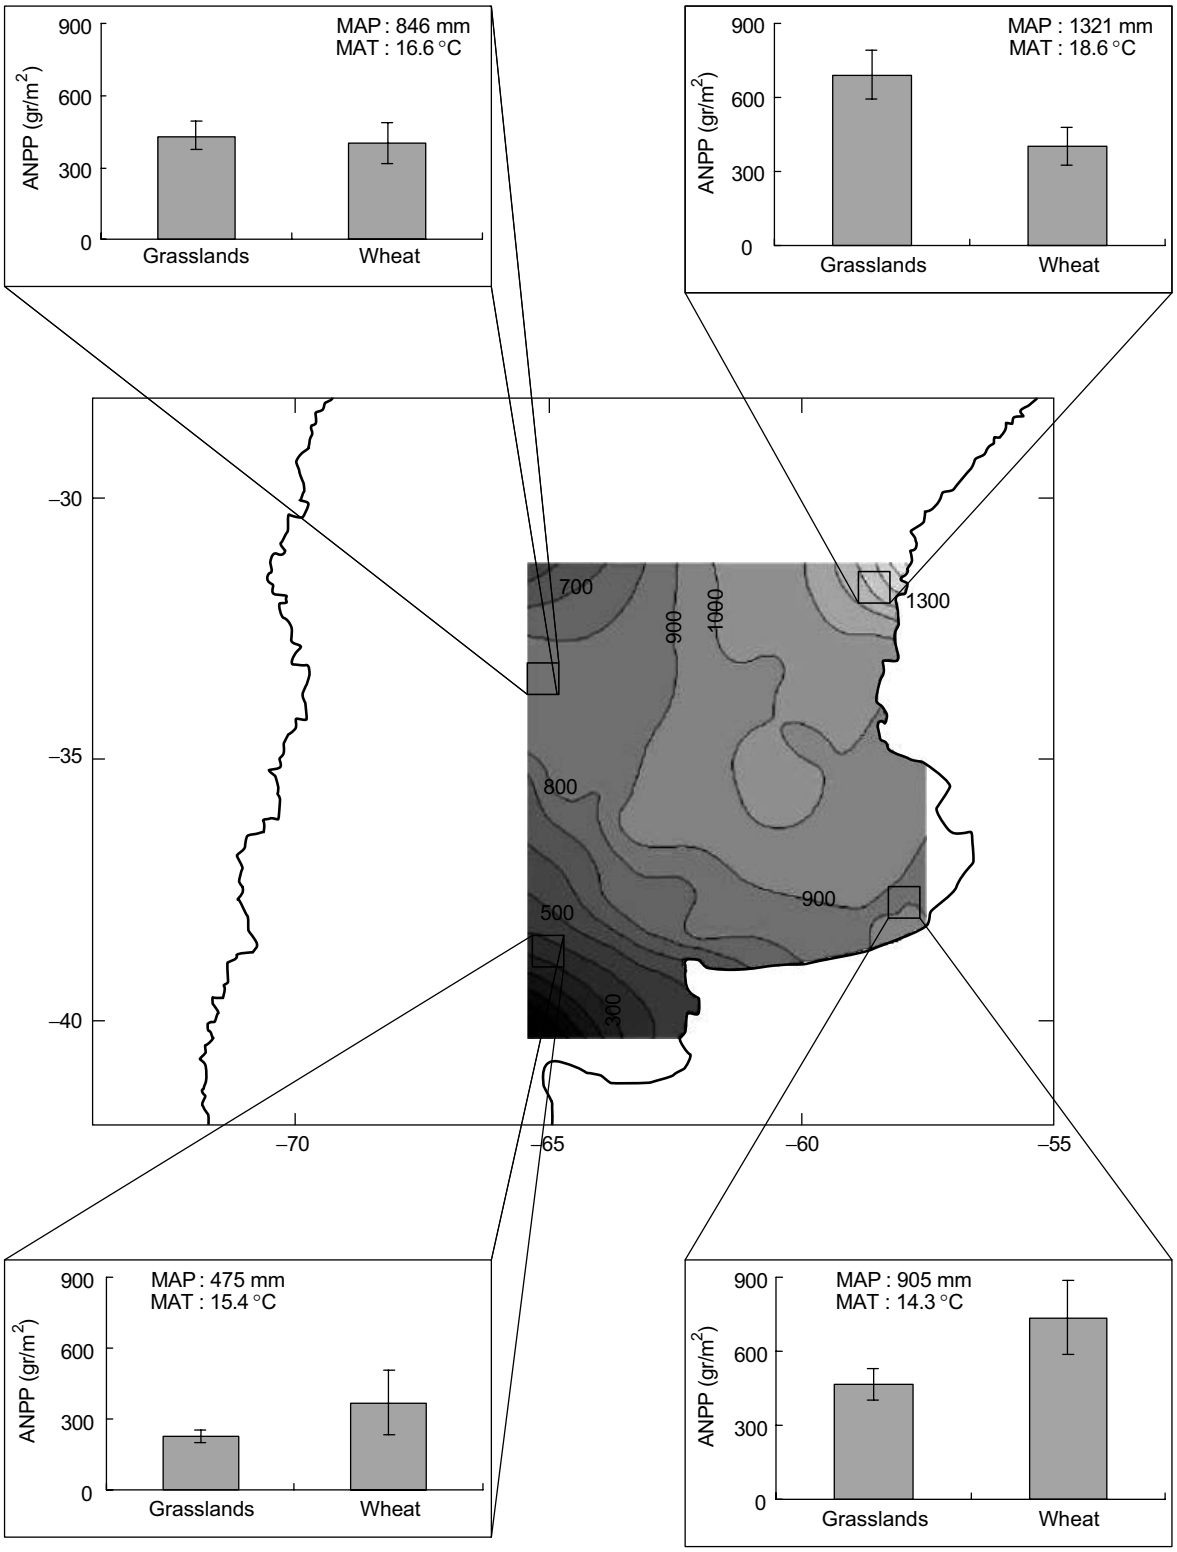

Figure 1 ANPP for wheat and grasslands sites located in the climatic extremes of the Pampas grasslands of Argentina. For wheat fields ANPP was estimated from grain yields (Argentine agricultural census) and harvest index. Wheat ANPPs are the average of 10 years. Small bars showed the temporal standard deviation. Grassland ANPPs are the average of estimates derived from four different models for the relationship ANPP- MAP (Sala *et al*., 1988; McNaughton *et al*., 1993; Paruelo *et al*., 1999 (two models)). Small bars corresponded to the standard deviation of the estimates derived from the different models. Isopleths correspond to mean annual precipitation

relationships suggests that the proportion of the ANPP consumed by herbivores increases with ANPP. The efficiency of energy transfer between trophic levels (animal production/net primary production) is higher in grasslands than in forests.

The disturbance regime affects carbon gains in grasslands. Fire reduces ANPP in the driest portion of a precipitation gradient (Oesterheld *et al.*, 1999). In subhumid grasslands, fire generally increases ANPP, except in dry years (Knapp *et al.*, 1998). In these grasslands, fire removes large amounts of above-ground dead material, increasing light and soil nutrient availability (Knapp and Seastedt, 1986). In dry years, this effect is less important than the reduction in evapotranspiration promoted by the detritus layer (Knapp *et al.*, 1998). Grazing may increase or reduce ANPP depending on the evolutionary history of grazing, MAP, and levels of consumption (Milchunas and Lauenroth, 1993). Over a broad range of grasslands, Oesterheld *et al.* (1999) found that, on average, grazing by large vertebrates slightly reduced ANPP.

Grassland biogeochemistry is largely controlled by precipitation, temperature and soil texture. Decomposition rates are more affected than ANPP by temperature. Given the same amount of precipitation, the consequence of the effect of temperature on decomposition is a higher accumulation of organic carbon in cold than in warm areas. Species composition, through litter quality, has a significant influence on decomposition rates and nutrient immobilization.

THE IMPACT OF GLOBAL CHANGE ON TEMPERATE GRASSLANDS

Land Use

Land cover changes associated with agriculture and grazing by domestic herbivores have had an enormous impact on the structure and functioning of grasslands. Agricultural practices have reduced soil carbon stocks by 35% in the US Central Grasslands during the last 50 years (Burke *et al.*, 1989). Based on carbon isotopic analyses, Wilson (1978) estimated that pioneer agriculture (1860–1890) in temperate areas of Australia, New Zealand, North and South America contributed one and a half times the amount of carbon dioxide (CO_2) produced by all the fossil fuels burnt before 1950. This reduction of soil carbon stocks results from an increase in decomposition rates due to plowing and a reduction of carbon inputs to the soil due to the low below-ground biomass of annual crops and to exports of above-ground biomass.

Land-use pattern has a critical influence on mesoscale atmospheric processes, and hence on local climate (Pielke *et al.*, 1997). Mosier *et al.* (1991) reported significant changes in trace gas fluxes associated with cultivation of a semi-arid grassland: agriculture increases the release of methane (CH_4) and nitrous oxide (N_2O), two greenhouse gases. These additions of CO_2 and other trace gases to the atmosphere may represent significant feedbacks to global climate change.

It is not clear to what extent agricultural practices modify total carbon gains. In the Pampas of Argentina, agriculture may increase or decrease above-ground net primary production relative to the native grasslands depending on environmental conditions (Figure 1). The difference in primary production between grasslands and wheat fields is higher in the wettest portion of the Pampas. In warm areas, grasslands are more productive than wheat fields. The opposite happens in the coolest part of the region.

Total carbon gains should be lower for agricultural fields than for native grasslands because below-ground production is one order of magnitude lower for crops than for grasslands. Land-use may modify not only total carbon gains but also the seasonal dynamics of leaf area index and intercepted radiation. Figure 2 shows the idealized course of the fraction of radiation intercepted by the canopy for different land covers. Curves were drawn from data provided by spectral indices derived from meteorological satellites (Advanced Very High Resolution Radiometer – National Oceanographic and Atmospheric Agency (NOAA/AVHRR)). Land use modifies both the intra-annual range of the fraction of intercepted radiation and the timing of maximum interception. These phenological changes modify the partitioning between latent and sensible heat and, consequently, they may affect the dynamics of the boundary layer of the atmosphere.

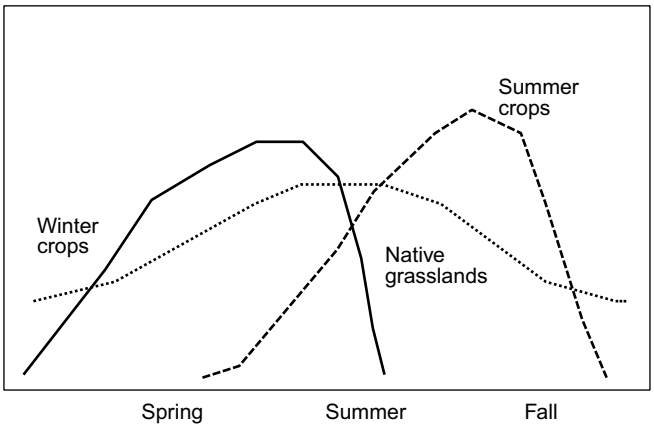

Figure 2 Seasonal dynamics of the fraction of radiation intercepted by the canopy from three land cover categories in the Argentine Pampas. Intercepted radiation is an estimator of ANPP. Curves were derived from normalized difference vegetation index data from NOAA/AVHRR satellites

Land use has increased the rate of species extinction not only by replacing natural ecosystems, but also by changing the disturbance regime. Leach and Givnish (1996) showed that 8–60% of the original plant species of remnant prairie sites were lost after 50 years due to landscape fragmentation or fire suppression. Changes in species diversity and composition have direct effects on the functioning of grasslands, affecting their productivity and stability.

The introduction of domestic herbivores promotes structural and functional changes in grasslands. A common effect of overgrazing in grasslands is shrub encroachment (Archer, 1994). The increase in shrub cover in grass steppes of Patagonia due to overgrazing (León and Aguiar, 1985) altered water dynamics, increased albedo, and reduced primary production and herbivore biomass (Aguiar *et al.*, 1996). Bryant *et al.* (1990) and Nasrallah *et al.* (1994) reported changes in surface temperature associated with overgrazing in southwestern USA.

Atmospheric Composition

Early experiments and photosynthetic theory suggested a differential response of C_3 and C_4 grasses to changes in atmospheric concentration of CO_2. C_3 and C_4 plants differ in their metabolic pathways of CO_2 fixation. In C_3 plants the first product of the photosynthetic CO_2 fixation is a phosphorylated three-carbon compound. In C_4 plants the first product is a four-carbon acid. C_3 and C_4 plants differ also in their leaf anatomy. Two different groups of photosynthetic cells are found in C_4 plants: mesophyllic and bundle sheaths cells. The latter surround the leaf vascular bundles and separate them from the mesophyllic cells. C_4 grasses present a CO_2 concentration mechanism in the bundle sheath cells that increases the effective concentration of CO_2 at the carboxylation site. Such a CO_2 pumping mechanism would saturate photosynthesis at current CO_2 levels. Therefore, it has been suggested that this plant functional group would not show a significant growth response to increases in atmospheric CO_2 concentrations. However, a meta-analysis by Wand *et al.* (1999) indicates that the response of wild C_3 and C_4 grasses to elevated CO_2 concentrations was surprisingly similar (*see also* **C_3 and C_4 Photosynthesis**, Volume 2).

At the leaf level, an increase in atmospheric CO_2 reduces stomatal conductance and increases net photosynthesis. A consequence of these changes is an increase in water use efficiency (WUE). Specific leaf area and nitrogen concentration are, in general, lower under elevated CO_2 concentrations. At the individual level these changes result in an increase in both above and below-ground biomass and in the number of tillers (Wand *et al.*, 1999). The mentioned analysis showed an overall increase in total biomass of 44% in C_3 species and of 33% in C_4 species.

Studies using open-top chambers allow one to explore changes at the population, community, and ecosystem level. These changes result not only from the effect of elevated CO_2 on plant production but also from major changes in soil water dynamics associated with changes in water use efficiency. Jackson *et al.* (1994) working in Mediterranean grasslands in California showed increases in density, seed production, and survival of the dominant grass *Avena barbata* under elevated CO_2. Changes in phenology associated with a delayed senescence have been reported in C_4 tallgrasses (Owensby *et al.*, 1997). In the tallgrass prairie of eastern Kansas (USA) an eight year long open-top chamber experiment provided no evidence for a replacement of the dominant C_4 grasses by C_3 grasses or forbs under elevated CO_2 concentrations (Owensby *et al.*, 1993). In these grasslands, the balance between C_3 and C_4 grasses seems to be more sensitive to the main disturbances (fire and grazing) than to CO_2 concentration. Elevated CO_2 decreased dominance in sub-humid temperate grasslands (Potvin and Vasseur, 1997) who showed a higher effect of elevated CO_2 on early successional species growth, which prevented the dominance of late successional ones.

Combining field data and simulation models, Jackson *et al.* (1998) showed that the direct effect of CO_2 on water use efficiency and total biomass production on Mediterranean grasslands affected water dynamics at the ecosystem level. Under elevated CO_2, plant transpiration was lower. Low transpiration at the beginning of the growing season increased soil water content and deep percolation. Studies based both on field experiments and on model simulations suggest that the observed increase in WUE at the ecosystem level would compensate for increases in potential evapotranspiration associated with climatic changes driven by greenhouse gases. Biogeochemistry models (BIOME-BGC, Century and Terrestrial Ecosystem Model) simulated net primary production responses to doubled atmospheric CO_2 for grasslands that range from 1–20% increase. *See also* **Biome–BGC Ecosystem Model**, Volume 2; **CO_2 Enrichment: Effects on Ecosystems**, Volume 2; **Plant Competition in an Elevated CO_2 World**, Volume 2.

Climate

Changes in climate are difficult to isolate from changes in CO_2 concentrations. Climate modifications not linked to the increase of greenhouse gases may occur, however, as a result of land-use changes (Nasrallah *et al.*, 1994; Pielke *et al.*, 1997). General circulation models simulate changes in temperature in temperate grasslands ranging between +2.3 and +6.2 for a doubled CO_2 scenario (Houghton *et al.*, 1992). Changes in mean annual precipitation may range from −2.6% up to 17.5%, depending on the GCM and type of grassland considered. For the Central Grasslands of the USA, an increase of 1° Celsius in mean annual temperature represents an increase in potential evapotranspiration of 50 mm.

Two main approaches have been used to explore the effect of climate on grasslands: warming experiments and simulations using climate change scenarios. Experimentally-heated plots in montane meadows showed significant differences in the timing and magnitude of net carbon fluxes (Saleska *et al.*, 1999). The reduction of primary production resulted from a combined effect of a reduction in soil moisture and a shift in plant community composition. Alward *et al.* (1999) showed that the observed increase in nocturnal minimum temperatures in a semi-arid steppe was correlated with a reduction in the net primary production of the dominant grass species, and with increased abundance and production of exotic species and C_3 forbs.

Model simulations indicated that climate change, by itself, increased net primary production in most of the grassland regions of the world and reduced soil carbon stocks everywhere. The combined effect of climate change and elevated CO_2 increased net primary production in all the sites studied and reduced carbon losses by half (Parton *et al.*, 1995).

Temperature Increase: Effects on Terrestrial Ecosystems

Lindsey E Rustad[1] and Richard J Norby[2]
[1]USDA Forest Service, Durham, NH, USA
[2]Oak Ridge National Laboratory, Oak Ridge, TN, USA

Temperature is a fundamental factor that affects the rates of most biological and chemical reactions in ecosystems, and thus plays an important role in regulating the flow of energy, water and nutrients within and through ecosystems. Indeed, with the exception perhaps of water, temperature influences a greater number of terrestrial ecosystem processes than any other element of global change, including elevated atmospheric carbon dioxide, atmospheric nitrogen and sulfur deposition, tropospheric ozone, and increased ultraviolet-B radiation. Although short-term responses to changes in temperature of individual ecosystem processes, such as photosynthesis and respiration, have been studied for well over a century, a comprehensive understanding of whole-ecosystem response to global warming remains elusive. This is because of the complex array of direct and indirect responses to changes in temperature, the variable time scale of response of different ecosystem processes and components to changes in temperature, and the importance of initial conditions (Shaver et al.*, 2000).*

These complexities are apparent when we try to predict the effect of warming on ecosystem carbon balances. The net carbon balance of an ecosystem, also known as net ecosystem productivity (NEP), represents the total amount of carbon fixed by an ecosystem minus the total amount of carbon respired or lost by an ecosystem. NEP is calculated as net primary production (NPP, or the total amount of CO_2-C fixed photosynthetically by plants each year minus the total amount of C respired by plants each year) minus heterotrophic respiration (R_h, or the total amount of carbon respired by animals and decomposers each year). Both NPP and R_h generally increase as temperatures increase, with R_h increasing somewhat more in the short term than NPP (Woodwell, 1995). Increases in temperature can, however, also indirectly affect NPP and R_h via changes in soil moisture, nutrient availability (particularly nitrogen and phosphorus), species composition, and interactions with other stress factors in complex ways that are not yet fully understood. Ultimately, a warming-induced change in NEP will depend on the relative sensitivity of NPP and R_h to changes in temperature. Understanding temperature effects on NEP is important because of the potential feedbacks to the climate system: an increase in NEP will remove carbon from the atmosphere, sequestering carbon in plant biomass, and thereby helping to ameliorate further increases in atmospheric carbon dioxide concentrations, whereas a decrease in NEP will exacerbate the already escalating increases in atmospheric carbon dioxide.

GLOBAL WARMING SCENARIOS FOR THE 21ST CENTURY

Recent evidence, including reports of warmer mean ocean temperatures, decreasing thickness of arctic sea ice, retreat of glaciers, earlier ice breakup on lakes and ponds, and analysis of long-term temperature records, suggest that mean global temperature has increased by 0.3–0.6 °C over the last 100 years, with the rate of warming showing the greatest increase over the last 20 years (Karl *et al.*, 2000). Current predictions based on General Circulation Models indicate that, unless greenhouse gas emissions are significantly curtailed, mean global temperature will increase by an additional 1–3.5 °C in the 21st century (Intergovernmental Panel on Climate Change (IPCC), 1996). The spatial and temporal variability in this increase is expected to be large. This is due in part to natural fluctuations in climate that occur on decadal time scales, and in part due to identifiable factors such as the thermal inertia of oceans. Specific predictions associated with climate change are that:

1. surface warming will be greater over the land than the seas in winter;
2. surface warming will be greater at higher latitudes than at the equator in winter;
3. little surface warming will occur over the arctic in summer;
4. nighttime minimum temperatures will increase proportionately more than daytime maxima;
5. there will be an increase in the occurrence of extremely hot days and a decrease in the occurrence of extremely cold days (Intergovernmental Panel on Climate Change (IPCC), 1996) (*see* **Projection of Future Changes in Climate**, Volume 1).

A CONCEPTUAL FRAMEWORK FOR EVALUATING ECOSYSTEM RESPONSE TO GLOBAL WARMING

Direct Effects of Warming on Ecosystems

Temperature directly influences the rates at which a wide range of chemical and biological processes take place. The increase in the reaction rate of biological processes per 10 °C increase in temperature is referred to as the biological Q_{10}, and is typically around two, or a doubling of biological reaction rates for every 10 °C increase in temperature from 0–~35 °C. Above ~35 °C, reaction rates typically decline rapidly due to the thermal denaturation of

proteins and cell membranes. Exceptions are found only in a few thermophilic, sulfur oxidizing bacteria, which can grow at temperatures of 80 °C or more.

All biological processes have a temperature optimum, with reaction rates increasing with increasing temperature from ~0 °C to the temperature optimum, and then declining rapidly with further increases in temperature. Thus, in order to understand and predict the biological response to an increase in temperature, it is important to know the temperature optima for a particular process. A 1–2 °C increase in temperature may increase rates for a specific process when temperatures are below the temperature optimum, but the same 1–2 °C increase in temperature could decrease rates if the temperature optimum for that process is exceeded. This is further complicated by the fact that biological organisms are typically adapted to regional climates, and thus temperature optimal vary regionally for the same process. For example, arctic and alpine plants typically have a lower optimum temperature (15–20 °C) for shoot and root growth than temperate species (25–30 °C). Furthermore, plants can acclimate to changing temperature by shifting their temperature optimum, as discussed below.

Temperature has profound direct influences on plant physiology, growth, and development through all life stages. Critical processes that are sensitive to temperature include seed germination, cell division and expansion, root and shoot growth, carbohydrate translocation, plant development and phenology, and flowering. Photosynthesis is sensitive to temperature primarily through the membrane-bound photochemical reactions, but the carboxylation efficiency of the primary photosynthetic enzyme is also sensitive to temperature. Respiration typically increases exponentially with increasing temperature. Increases in temperature beyond the thermal tolerance limit can cause irreversible damage to the photosynthetic membranes. Mitochondria (organelles found in plant cells responsible for aerobic respiration), in contrast, are more stable, so respiration continues to increase as photosynthesis declines (Weiss and Berry, 1988). Volatilization of hydrocarbons from plants increases with temperature, representing a loss of carbon. The net effect of the many different influences on carbon gains and losses can be difficult to predict, but generally NPP increases with modest increases in temperature.

At higher latitudes and higher elevation, plant growth is constrained to a large extent by low winter temperatures and the length of the growing season. Global warming can be expected to lengthen the growing season in temperate zones. Indeed, several lines of evidence suggest that the start of the growing season in the Northern Hemisphere has already advanced by seven days since 1958 (Myneni *et al.*, 1997). The length of the growing season is an important determinant of annual NPP, accounting for much of the inter-annual variation in NPP for a given site, as well as for NPP differences between sites at different latitudes. Phenological events such as bud break in spring and senescence and dormancy in fall are controlled by a complex suite of environmental signals including not only temperature but also photoperiod, which is not subject to anthropogenic perturbation. Climatic warming may create disjunction between the temperature and photoperiodic influences on phenology, and surprises such as insufficient winter chilling or untimely frosts could sometimes decrease NPP (Norby *et al.*, 2000) (*see* **Phenology**, Volume 2).

Temperature also directly influences processes mediated by soil micro- and macro-organisms. Soil micro- and macro-organisms play a dual role in terrestrial ecosystems. (1) They serve as a sink for carbon and nutrients during periods of population expansions, and a source of carbon and nutrients during periods when populations are declining; and (2) they are the agents of many biochemical processes fundamental to nutrient cycling. These processes include *decomposition* of plant and animal residues (thereby releasing carbon back to the atmosphere largely in the form of carbon dioxide and releasing nutrients back to soils and surface waters), *ammonification* (the transformation of organic N to NH_4), *nitrification* (the transformation of NH_4 to NO_3), *denitrification* (the transformation of NO_3 to NO and N_2O), and *methane reduction and oxidation*. In general, these processes speed up with increasing temperature. As with net ecosystem carbon balance, temperature effects on soil organic matter (SOM) will reflect the balance between increased litter inputs (as a result of increased NPP) and increased rates of litter decomposition. In general, SOM declines with increasing temperature, as evidenced by the documented global trends of declining SOM with decreases in latitude or altitude. SOM is important because of its contribution to soil nutrient status, soil water holding capacity, and soil texture.

Indirect Effects of Warming on Ecosystems

Temperature can also influence ecosystems and ecosystem processes through multiple, indirect pathways, particularly those involving temperature-induced changes in water, nutrients, species composition, and the activity of herbivores and pathogens. For example, temperature and water are closely linked, and many of the effects of temperature on ecosystems occur through changes in evapotranspiration and soil moisture. Although the water-holding capacity of the atmosphere increases with temperature, the vapor pressure gradient from leaf or soil to air also increases. Hence, plant transpiration and direct evaporation from soil are higher at warmer temperatures. Increased drought is a prominent prediction of climate warming models (Intergovernmental Panel on Climate Change (IPCC), 1996), and drought is an important determinant of NPP. Soil moisture strongly controls microbial processes, including litter

decomposition and nutrient cycling, and is an important mediator of the diffusion of ions to root surfaces. The indirect effects of temperature increases via soil moisture deficits on plant and soil metabolism are opposite in sign from many of the direct effects of temperature, and they could be the dominant signal in many ecosystems. For example, tree ring analysis of Alaskan white spruce (Barber *et al.*, 2000) suggests that despite the apparent increase in the length of the growing season at high northern latitudes, radial growth has declined in response to increasing temperature and temperature-induced drought stress.

Temperature-induced changes in nutrient availability can also have a large, albeit indirect, impact on ecosystems. Increasing temperature can increase nutrient availability by: (1) increased rates of litter decomposition, and thereby more rapid release of nutrients from decomposing organic matter; (2) increased rates of nitrogen mineralization and nitrification; and (3) increased rates of chemical diffusion to the root surface.

Direct or indirect effects of temperature on the populations and/or activity of herbivores and pathogens could have profound effects on ecosystem structure and function by changing the amount and timing of detrital inputs to the soil, and by dramatically altering species competitive interactions. Changes in species composition can, in turn, affect a multitude of other ecosystem properties, such as plant growth rates, litter quantity and quality (and consequently microbial dynamics and litter decomposition), canopy structure and architecture, shading, and rooting depth, to name a few.

Variable Time Scale and Direction of Response

The time scale of ecosystem response to warming ranges from the millisecond to the millennium. At the very short time scale (seconds to days), warming directly influences the rates of chemical and biological reactions, as discussed above. At the month-to-seasonal time scale, warming can influence ecosystem carbon and nutrient allocation, nutrient mobilization and immobilization, and microbial species composition. At the annual-to-decadal time scale, warming can influence plant species competitive interactions, litterfall quantity and quality, and herbivore and pathogen dynamics. Over time scales ranging from several decades to several centuries, sustained increases in temperature can result in shifts in species composition (including migration of species to higher latitudes and higher elevations, and invasion of new, exotic species), changes in soil and SOM development, altered susceptibility to herbivores and pathogens, and changes in ecosystem disturbance regimes, particularly susceptibility to fire, as ecosystem fuel loads increase or decrease.

Changes in both the direction and the magnitude of response over time are possible, representing a changing sequence of controls. For example, plant growth may initially increase with warming due to higher rates of photosynthesis and longer growing seasons. Over time, however, this increased growth may not be sustained due to depletion of available soil nutrients, and growth rates may return to previous or even below previous levels. Similarly, the short-term (days–months) rates of microbial respiration typically increase with increasing temperature. This can continue as long as labile (i.e., chemically unstable) carbon sources are available. As these labile carbon sources are depleted, rates of microbial respiration may decline, despite higher temperatures. Litter decomposition also generally increases with increasing temperature if moisture remains adequate. However, changes in plant growth rates or changes in species composition can result in changes in the quality of litter over time. If litter quality declines, rates of litter decomposition may decline despite increased temperature.

Finally, the response of individual species to sustained increases in temperature may change over time as plants and soil organisms become acclimated to changing conditions. Because of this acclimation, much of our understanding of ecosystem response to changing temperature comes from time scales that may not be completely relevant to global change analyses. Over the short-term (hours), for example, autotrophic respiration responds to temperature by the Arrhenius function, but as a plant acclimates to a higher temperature, its respiration rate is reduced at a given temperature. Global change predictions that assume a Q_{10} of two for plant respiration will almost certainly overestimate the increase in respiration resulting from increases in temperature occurring over decades. Similarly, photosynthesis acclimates to temperature, but here the analysis is more complicated. Patterns of photosynthetic acclimation to temperature include a shift in the optimum temperature or an adjustment in the rate at all temperatures (Gunderson *et al.*, 1999). Membrane-bound processes such as ion uptake acclimate to changes in temperature through changes in the lipid composition of the membranes, so short-term responses of ion uptake to temperature probably are not relevant to changes in mean annual temperature occurring over decades.

Adjustments in soil processes to temperature changes will have different characteristics from adjustment processes in plants because of the rapid turnover of microbial populations. There have been suggestions that R_h (i.e., animal and decomposer respiration) acclimates to increased temperature and that Q_{10} representations are not appropriate (Giardina and Ryan, 2000). However, it can be difficult to separate the effects of temperature and soil moisture, which also has a large effect on soil microbial activity. On a global scale, fine root turnover (an important source of carbon to soil) is higher at higher temperatures, but this pattern is not apparent at specific sites subjected to warming (Gill and Jackson, 2000). As with other plant growth processes, there is evidence that root production acclimates to higher

temperature (Fitter *et al.*, 1999), and other factors such as stimulation of aboveground production or indirect effects on nutrient availability are likely to be more important controls on root production than temperature alone.

Since short-term temperature manipulations may provide misleading answers to longer-term responses, it is useful to study patterns of temperature response across the landscape, analyzing the relationship between fully acclimated populations of plants and the prevailing temperature regime. Such studies generally reveal broad patterns of NPP versus mean annual temperature, which might provide a basis for predictions of response to climatic change; an approach known as substituting space for time. But this approach also requires caution. Much of the basis for increased NPP at higher temperature is attributable not to a primary response of the instantaneous balance between photosynthesis and respiration, but to the increased length of the growing season at lower latitudes under current climate, and the length of the growing season is controlled in part by day length; one global factor that will not be affected by human activity. Another confounding factor with application of natural temperature gradients as an analog for climatic warming is that plant populations adapt to the prevailing climate via genetic change, a process that is not relevant to long-lived organisms (e.g., trees) over the several decade period of relevance to policy makers.

Importance of Initial Conditions

Overlaid on the aforementioned complexities in determining the direction and magnitude of ecosystem response to warming is the importance of initial conditions. For example, a $1-2\,^{\circ}C$ increase in temperature could increase productivity and plant growth in a moist, temperate forest ecosystem, but the same increase in temperature could result in significant declines in productivity in a hot, dry desert ecosystem due to additional moisture and high temperature stress. Or an increase in temperature could increase productivity in an ecosystem with high initial stocks and turnover rates of available nitrogen, but could have no effect on productivity in a nitrogen-limited ecosystem. Or an increase in temperature could result in a better competitive advantage for a species at the northern limit of its range, whereas the same increase in temperature could reduce the competitive advantage of the same species already at the southern limit of its range. Shaver *et al.* (2000) suggested that the following list of initial conditions should be considered when assessing ecosystem responses to warming:

1. stocks and initial turnover rates of labile soil carbon;
2. stocks and initial turnover rates of labile soil nitrogen;
3. relative size of the carbon pools of plants and soil;
4. dominant form of available nitrogen in the soil (e.g., organic nitrogen, ammonium, nitrate);
5. soil water and precipitation regime;
6. chemical composition and turnover rates of live plant tissues and litter;
7. longevity of individuals and population turnover rates of dominant plant species.

The time scale of response and the major controls on response will thus vary in different ecosystems. For example, in ecosystems where the dominant vegetation is long-lived trees, changes in soil nutrient availability may have a greater impact on total ecosystem productivity on the annual to decadal scale, whereas in ecosystems where the dominant vegetation is short-lived grasses, changes in species composition may be more important.

Interactions With Other Elements of Global Environmental Change

Ultimately, the effects of elevated temperature on terrestrial ecosystems must be understood in the context of concomitant changes in other elements of global environmental change, including higher atmospheric carbon dioxide concentrations, regionally variable atmospheric nitrogen inputs, and both increases and decreases in precipitation. Elevated atmospheric carbon dioxide concentrations, for example, are expected to stimulate plant productivity and increase the flux of carbon to soil. This could partially or completely offset the carbon loss from soil resulting from concurrent increases in temperature. For nitrogen, which is generally considered to be one of the key limiting nutrients in terrestrial ecosystems (Vitousek *et al.*, 1997), a warming-induced increase in the internal production of inorganic nitrogen (nitrogen mineralization, *see* **Nitrogen Mineralization**, Volume 2) could stimulate plant growth and NEP at nitrogen limited sites. This would effectively transfer nitrogen from soil pools with typically low ratios of carbon to nitrogen (carbon/nitrogen of 30 or less) to plant biomass pools, with typically higher ratios (carbon/nitrogen ratios >30). Because of these higher carbon/nitrogen ratios, the same amount of nitrogen can support a greater net storage of carbon in an ecosystem. However, in nitrogen-sufficient or nitrogen-rich environments, particularly those in the Northern Hemisphere which are already impacted by elevated atmospheric nitrogen deposition, a warming induced increase in internal nitrogen production could lead to, or further exacerbate, conditions of nitrogen saturation, where the input of nitrogen equals or exceeds the ability of an ecosystem to assimilate the added nitrogen (Aber *et al.*, 1998). Symptoms of nitrogen saturation include nutrient imbalances in plant tissues, forest decline, increased gaseous loss of nitrogen, and increased nitrogen leaching from soils with consequent declines in associated surface water quality (Vitousek *et al.*, 1997) (*see also* **Nitrogen**

Cycle, Volume 2; **Nitrogen Deposition on Forests**, Volume 2). Changes in precipitation regimes could dramatically alter responses to warming alone because of the many interactions between temperature and water, as discussed previously. Increased precipitation could offset the increased water loss due to warming-induced increases in evapotranspiration, thereby preventing low-moisture stress, and resulting in higher NPP. Reduced precipitation, on the other hand, could exacerbate low-moisture stress, resulting in declines in ecosystem productivity.

ECOSYSTEM WARMING EXPERIMENTS: EVIDENCE OF RESPONSE TO WARMING

Over the last 5–10 years, as global warming predictions have become more widely accepted, the need for information on the response of ecosystems to changing temperature has been addressed by a growing number of ecosystem warming experiments that have been initiated around the world. Although these studies do not perfectly simulate the expected increase in temperature which will occur on the decadal-to-century time scale, and few of these studies have evaluated interactions between elevated temperature and other elements of global change, these experimental manipulations do provide a useful tool to (a) test conceptual and quantitative models of ecosystem response to warming, and (b) begin to evaluate what kinds of ecosystems and which ecosystem processes are most sensitive to warming.

Consistent with the conceptual model of multiple, interacting direct and indirect responses to warming occurring over variable time scales, results from this first decade of ecosystem warming experiments have been highly variable in time and space, making general response patterns difficult to identify. For example, at different sites, experimental warming has resulted in increases, decreases, and no response in ecosystem processes such as soil respiration, litter decomposition, methane production and oxidation, nitrogen mineralization, and plant productivity. To address these apparently different responses to experimental warming, Rustad *et al.* (2001) synthesized results on the response of soil respiration, net nitrogen mineralization, and aboveground plant productivity to experimental warming at sites associates with the Global Change in Terrestrial Ecosystem's Network of Ecosystem Warming Study Sites (GCTE-NEWS). Arft *et al.* (2000) synthesized results on the response of plant productivity and reproductive success to experimental warming at sites associated with the International Tundra Experiment (ITEX), as summarized below. Both syntheses used *meta-analysis* to evaluate responses to warming. Meta-analysis is a technique developed specifically for the statistical synthesis of independent experiments (*see* **Metadata**, Volume 2).

The GCTE-NEWS Synthesis

The GCTE-NEWS includes 32 experimental warming sites, representing four broadly defined biomes: high tundra, low tundra (including a temperate peat bog), forest, and grassland. Warming methods included electrical heat resistance ground cables, greenhouses, open top chambers, climate controlled chambers, and passive night time warming. The duration of these studies ranged from two to nine years, and the experimental increases in soil or air temperature (whichever was the target) ranged from 0.3 to 6.0 °C, with a mean increase of 2.4 °C across all 32 studies.

Data on the response of soil respiration (which represents the combined respiration of roots and soil micro- and macro-organisms) to experimental warming were available at 17 of the 32 GCTE-NEWS sites. Across these 17 sites, experimental warming significantly increased rates of soil respiration by a mean of 20% (with a 95% confidence interval of 18–22%). Such an increase in soil respiration would correspond to an increased release of $\sim$14–20 Pg C year^{-1} from the soil to the atmosphere, based on estimates of annual global soil respiration ranging from 68 Pg C year^{-1} (Raich and Schlesinger, 1992) to 100 Pg C year^{-1} (Musselman and Fox, 1991). This increase is two to three times the estimated $\sim$7 Pg C year^{-1} of carbon dioxide currently released to the atmosphere via combined fossil fuel combustion and land-use changes (Lal *et al.*, 1995), and could significantly exacerbate already escalating atmospheric carbon dioxide concentrations and further disrupt the global carbon balance and global climate system. Caution must be exercised, however, in extrapolating results from experimental warming studies to a global basis, particularly as it is possible that the observed increases in soil respiration are, at least in part, a transient response, reflecting the oxidation of only the most labile soil carbon compounds. Once the labile soil carbon fractions are decomposed, the response of soil respiration to experimental warming may decline. The magnitude and duration of the response of soil respiration to warming will also likely be influenced by changes in the quantity and distribution of precipitation, or warming induced declines in soil moisture, as discussed previously. Site specific studies have shown a negative response of soil respiration to elevated temperature under situations where soil moisture becomes limiting (e.g., Harte and Shaw, 1995).

Data on the response of net nitrogen mineralization (*see* **Nitrogen Mineralization**, Volume 2) in the upper organic soil horizons to experimental warming were available at 12 of the 32 GCTE-NEWS sites. Across these 12 sites, experimental warming significantly increased rates of upper organic soil horizon net nitrogen mineralization by a mean of 46% (with a 95% confidence interval of 30–64%). Gross rates of nitrogen mineralization were probably higher than the values reported here for net mineralization, because

a large percentage of total mineralized nitrogen is typically quickly taken up and immobilized by the microbial community, particularly at nutrient-limited sites. For the 12 sites in the GCTE-NEWS synthesis, a 46% increase in net nitrogen mineralization corresponded to an increased internal production of 4.8 kg N ha^{-1} $year^{-1}$. This compares to atmospheric wet plus dry deposition inputs ranging from <5.0 kg N ha^{-1} $year^{-1}$ in relatively pristine areas to 50 kg N ha^{-1} $year^{-1}$ or more in the heavily polluted areas of the northeastern US and Europe (Vitousek *et al.*, 1997).

Data on aboveground plant productivity response to experimental warming were available at 20 of the 32 GCTE-NEWS sites. Across these 20 sites, experimental warming significantly increased rates of aboveground plant productivity by a mean of 19% (with a 95% confidence interval of 15–22%). Increases in plant productivity would result in a greater storage of carbon in plant biomass (especially in systems with a significant woody component) and increased flux of carbon to soils in leaf and root litter. This could at least partially offset the warming-induced increase in carbon flux from soils to the atmosphere via soil respiration.

The ITEX Synthesis

The ITEX is a collaborative, multi-site experiment using a common open top chamber experimental design to evaluate variability in species response to warming in tundra ecosystems. Arft *et al.* (2000) examined the response of plant phenology, growth, and reproduction to 1–4 years of experimental warming at 13 circumpolar sites. Results showed different pathways of response in time and space. For example, although key phenological events such as leaf bud burst, flowering, and seed dispersal generally occurred earlier in warmed plots compared to control plots throughout the four years of the study, plant productivity was greater in the warmed plots than the control plots during the first 2–3 years of the experiments, whereas reproductive effort and success increased in later years, particularly in year four. Arft *et al.* (2000) attributed the decrease with time in plant productivity response to warming in part to a depletion of belowground resources. They attributed the delayed reproductive response to the fact that flower buds are typically formed from one to several seasons before flowering. Arft *et al.* (2000) further showed that: (1) the vegetative response to warming differed among plant life forms, with the response being generally greater in herbaceous than woody species; (2) warmer, low arctic sites showed the strongest growth response to warming; and (3) colder, high arctic sites showed the strongest reproductive response to warming. Overall, these differential responses to warming observed among sites, life forms, and over time are consistent with the conceptual model of ecosystem response to warming reviewed above, and underscore the need to evaluate ecosystem response to warming at different temporal and spatial scales.

CONCLUSIONS

There is no question that concentrations of atmospheric carbon dioxide and other greenhouse gases have increased dramatically over the last century due to human activities. The evidence continues to accumulate that this increase in greenhouse gas emissions has been and will continue to be accompanied by increases in mean global temperature. Because temperature is a fundamental driver of most chemical and biological reactions, these human-induced changes in thermal regimes will have a multitude of direct and indirect effects on terrestrial ecosystems at multiple spatial and temporal scales. Predicting the response of whole ecosystems to increases in temperature will therefore be difficult, and will require continued refinement and integration of conceptual and quantitative models of short- and longer-term ecosystem response to increased temperature.

Completed and ongoing ecosystem warming experiments have proven useful tools to explore the response of ecosystems and ecosystem components to experimental warming, and have shown conclusively that increases in temperature in the range of 0.3–6.0 °C can have significant impacts on fundamental ecosystem processes, including soil respiration, nitrogen mineralization, and plant growth, phenology, and reproductive success. Future ecosystem warming experiments need to: (1) more fully integrate the experiments at the ecosystem level, including both aboveground and belowground processes. (2) Investigate interactions with other vectors of environmental change, especially water, carbon dioxide, nitrogen deposition, and tropospheric O_3; and (3) expand the spatial and temporal scales of analysis, including additional experiments in under-represented biomes, such as tropical, desert, and Mediterranean ecosystems, and over longer time periods.

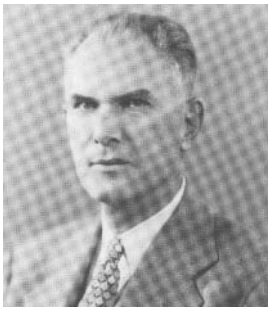
Thornthwaite, Charles Warren



(1899–1963)

Charles Warren Thornthwaite changed the course of climatology in the 20th century by stressing that climatology was not solely the realm of the geographer, but belonged also to the botanist, hydrologist and engineer. He was the founder of the field of applied climatology. His water budget model has been used by hydrologists as a means of quantifying the hydrologic cycle, to estimate surface runoff where no data exist, and to extend the runoff record back in time. It provides data on soil moisture and evapotranspiratiion of benefit to agriculture and forest scientists, and estimates of water deficiency useful to crop scientists and irrigation engineers. In recent years, it has been widely applied in studies of the impact of climate change on water resources.

Charles Warren Thornthwaite was born in 1899 on a farm in central Michigan (USA). After graduating from Central Michigan University he became a high school teacher, but at the age of 25 was persuaded by friend John Leighly to take graduate work in geography at the University of

California. After receiving his PhD from UCLA he became a professor of geography at the University of Oklahoma. Until this time he had shown little interest in climatology, but living in the dry state of Oklahoma made him realize the importance of water. In his first climatic publication (in 1931) *The Climates of North America According to a New Classification* he used evaporation data to derive precipitation/evaporation indices.

During the depression years of the 1930s President Roosevelt established the Soil Erosion (later Conservation) Service in the Department of Agriculture in Washington and in 1935, Thornthwaite was appointed head of the Climatic and Physiographic Research Branch of this Service. The appointment marked a change in Thornthwaite's life and the beginning of his career in climatic research. He obtained large grants for his research in the loss of water from land to air, first in western Oklahoma and later in Arizona and Ohio. Much of this research was published in the 1941 Yearbook of Agriculture *Climate and Man*.

During the World War II years, Thornthwaite continued his climatic research as a consultant in irrigation to the Mexican Government. He revised his 1931 climate classification paper using actual water use data. *An Approach Toward a Rational Classification of Climate* published in 1948 was undoubtedly the most important of his writings. The central concept of the revision was *potential evapotranspiration*, defined as the amount of water that would be lost from a vegetated surface by evaporation and transpiration if an unlimited supply existed. He formulated a water budget model in which the need for water (potential evapotranspiration) was compared with the water supply (precipitation plus soil moisture) to derive quantitative estimates of actual evapotranspiration, water surplus and water deficiency.

Thornthwaite was also interested in practical applications of his research and in 1946 combined theory and practice by becoming a consulting climatologist to Seabrook Farms in New Jersey, one of the world's largest vegetable growers. He advised Seabrook on scheduling the planting and harvesting of peas, and a method of disposing of wastewater by irrigation. He also realized a life-long dream of a climatic research institute by forming a Laboratory of Climatology to conduct research and, in collaboration with The Johns Hopkins University, to train students in climatology. Research at the laboratory included the measurement of vertical gradients of wind, temperature and humidity, and of potential evapotranspiration by evapotranspirometer tanks. The laboratory also designed and manufactured instruments such as net radiometers and wind profile systems.

During the 1950s and 1960s many famous climatologists visited the laboratory: Anders Ångström and C C Wallén from Sweden, Rudolf Geiger from Germany, C E P Brooks and Howard Penman from England, Ken Hare from Canada and Helmut Landsberg and Heinz Lettau from the United States. Thornthwaite received many honors. In 1951 he was elected president of the Commission of Climatology of the newly established World Meteorological Organization. He was elected president of the American Association of Geographers and was awarded the Cullum medal by the American Geographic Society.

Tropical Forests

Ghillean T Prance
University of Reading, Reading, UK

Tropical forests are renowned for their species diversity and harbour more than 50% of the world's species. Tropical forests are the source of many well-known products of economic importance such as rubber, cacao and coffee. Concern is expressed about the amount of tropical deforestation in recent years and its effect on species loss and worldwide climate patterns.

The type and structure of tropical forest vary principally with altitude, soil, flooding regime, and rainfall patterns. The three main blocks of tropical forests occur in Amazonia, West and Central Africa, and in Southeast Asia, but tropical forest also occurs on many tropical islands in the Caribbean and the Pacific.

A large part of the tropical belt is covered by a variety of forest types. These vary mainly according to the climate, soil, topography and flooding regime. The major types of tropical forest are given in Table 1, but each of these categories can be subdivided in many different ways. Floristically, tropical forests divide into three main regions, each with its own group of species of plants and animals.

Table 1 Principal types of tropical forest[a]

1 Tropical evergreen forest (rainforest)

A seasonal forest with mostly evergreen species that have little or no bud protection against cold or drought

(a) Lowland rainforest: multilayered, many trees exceeding 30 m in height, closed canopy with sparse undergrowth, large lianas frequent, epiphytes relatively scarce

(b) Montane rainforest: few trees exceeding 30 m, palms and tree ferns common in undergrowth, ground layer rich in herbs and mosses, epiphytes common; often subdivided into lower montane and upper montane rainforest

(c) Cloud forest: high altitude closed forest with many gaps, trees rarely over 20 m, often gnarled, numerous lianas, tree ferns, herbs, shrubs and abundant epiphytes

(d) Alluvial forest: forest growing in seasonally inundated areas along river banks, multilayered, closed forest with numerous gaps, buttresses and stilt roots common, palms, herbaceous undergrowth and lianas common, epiphytes common

(e) Swamp forest: forest on permanently wet areas, buttresses, stilt roots and pneumatophores common, palms, ferns and herbs abundant

(f) Peat forest: forest over deep peat deposits in nutrient poor soils mainly in tropical Asia. Rarely above 20 m in height, ground cover mostly of ferns

2 Tropical monsoon forest

Forest with high, but strongly seasonal rainfall, largely evergreen, but more leaf shedding in dry season, trees of canopy moderately drought resistant, tree ferns absent in montane forest, but climbers and evergreen shrubs common, dense canopy with little undergrowth. Often divided into lowland and montane monsoon forest

3 Tropical semi-deciduous forest

Trees of upper canopy shed leaves in strong dry season, small trees and shrubs usually evergreen, open with shrubs, herb and tree saplings abundant, epiphytes rare

4 Mangrove forest

Single layered forests to 30 m height growing in intertidal zones in salt water throughout tropics and subtropics, evergreen, stilt roots and pneumatophores common, little ground vegetation, few epiphytes

[a] Adapted from Longman and Jenik (1987).

The largest area of tropical forest occurs in Central and South America and accounts for 54% of the total. West and Central Africa have about 18% and the East Asian tropics have 27%. Small areas also occur in various islands in the Caribbean and Pacific regions. Although the flora and fauna in each region are different, the structure and appearance of the various types of tropical forest are quite similar on the different continents.

The term *rainforest* was first used by Schimper (1903), one of the founding fathers of plant geography. He defined it as "evergreen, hygrophilous in character, at least 30 m high, rich in thick-stemmed lianas and in woody as well as herbaceous epiphytes". The term should be confined to the aseasonal, evergreen, multi-layered forest types. The term *tropical moist forest* extends beyond this to other closed canopy tropical forests where the annual rainfall is high (over 2000 mm) but seasonal such as in areas influenced by monsoons.

Lowland rainforest is characterized by its division vertically into three or four relatively distinct strata. The canopy level varies between 30 and 60 m. It tends to be taller in the forests of tropical Asia that are dominated by species of the plant family Dipterocarpaceae, than in the American forests. Above the canopy are a number of emergent trees that can reach 70–80 m in Asia (e.g., *Koompassia excelsa*). Emergents in the Amazon rainforest include the Brazil nut, *Bertholletia excelsa* and the enormous legume tree *Dinizia excelsa*. The strata are not always very distinct, but below the canopy, there are often layers of middle sized trees (10–25 m) and of lower trees (5–10 m). This layer is often of saplings of the larger trees, but each layer has characteristic species of trees that reach only to that height. Below the tree layers are the shrub and herb layers. Very little light reaches ground level (about 3% of what falls on the canopy), and so species of the rainforest are adapted to growing in conditions of extremely low light intensity. This is why some of them (e.g., *Philodendron* and *Calathea* species) make good houseplants since they can grow in shady rooms. The shrub layer is usually poorly developed in dense rainforest. The lowland forests consist largely of broad-leaved evergreen tree species. Large woody vines (lianas) are relatively common especially in Amazonian forests, but are much rarer in the lowland forests of tropical Asia and the Pacific.

At higher elevation, on tropical mountains, the climate is cooler and often wetter and the trees are smaller, the canopy more open and there are many more understory plants. Vegetation ecologists recognize a gradual progression of forest types from *lower montane forest* to *upper montane forest*, and finally, *cloud forest* at the highest elevations to sustain forest. The latter type is low in stature, with gnarled trees and an extremely rich epiphyte flora (plants not rooted in soil). Epiphytes are plants that live on the branches of other plants, but unlike parasites, do not draw nutrients

from their host. In its most reduced form, cloud forest is sometimes called *elphin forest*. There is a tendency towards smaller leaves as altitude increases. Lower montane forests are lower and less species rich than lowland forest and usually have only two strata. There are more epiphytes in this forest. Upper montane forests have even lower canopies at less than 20 m. There are no climbers, but epiphytes are abundant. In some areas single species dominate montane forests.

In regions where the rainfall is more seasonal, such as on the southern borders of the Amazon forest, in parts of Central America and in the monsoon areas of southern India and Myanmar (formerly Burma), the forests are progressively more deciduous, depending upon the length of the dry season. Tropical monsoon forests are mainly evergreen, but the canopy trees show drought-resistant adaptations. In tropical semi-deciduous forests, which occur in areas with a long dry season, the trees of the upper canopy shed their leaves in the dry season, but many of the small trees and shrubs remain evergreen.

Areas that are liable to flooding have different types of forest adapted to the flooding regime. They are less species diverse in terms of trees than the lowland forests on non-flooded ground. *Alluvial forests* exist in areas liable to flooding by the rising river levels of the rainy season, by far the greatest area occuring in Amazonia. The term used in Amazonia for areas flooded by white water rivers is *várzea* forest, whereas areas flooded by black and clear water rivers such as the Rio Negro (black water) and the Rio Xingu (clear water) is called *igapó* in Brazil. The flooded forests of Amazonia were divided into seven categories by Prance (1979). In the Amazon delta region, the river flow is blocked by tidal movements and there is a considerable area of forest which is subjected to twice daily inundation and is known as *tidal várzea*. Structurally and floristically, it is similar to the seasonally flooded várzea but has a greater quantity of palms. Swamp forest is forest on poorly drained areas that are permanently waterlogged. The tree flora is less diverse, palms are abundant and such adaptations as buttressed trunks, stilt roots and pneumatophores (aerial breathing roots) are frequent. Ferns are often abundant in the ground cover. In Asia, especially in Borneo, there is another type of swamp forest over peat. The peat forests have nutrient-poor soils and as a result are rarely over 20 m tall and are less species diverse than the drier forest types. Some peat swamp is dominated by palms, and other areas by broad-leaved trees.

Mangrove forests occur in intertidal zones throughout the tropics and subtropics. They are characterized by the stilt roots of several species and the presence of pneumatophores in many. This forest type is evergreen and single layered and adapted to growth in salt water. Mangroves play an essential role in the stabilization of tropical coast lines. They also support a wide range of wildlife and are equally important as a source of fish and crustaceans. Their rapid destruction is causing loss of income for local fishermen and serious problems of erosion (*see* **Mangrove Ecosystems**, Volume 2).

The largest and still the most intact tract of tropical forest is that of the Amazon Basin, which contains almost 50% of the total, but other important areas of tropical forest also occur in the Americas. Tropical forests reach as far north as Mexico, where they are mainly semi-deciduous and extend in patches throughout Central America. West of the Andes, the coastal region of Colombia (the Chocó) and northern Ecuador is the wettest rainforest in the world (precipitation up to 6000 mm $year^{-1}$), and it contains a large number of endemic species of plants, especially in the shrub and herbaceous layers. The other important neotropical rainforest area is a narrow belt along the Atlantic coast of Brazil from the State of Ceará in the north to São Paulo in the south. Unfortunately, less than 6% of the *Mata Atlantica* remains intact. It contains many endemic and threatened species of plants and animals such as the golden lion tamarin (*Leontopithecus rosalia rosalia*).

The African tropical forests mainly occur in West and Central Africa with a few small, scattered patches extending into East Africa. The forests of West Africa have largely been destroyed and the remaining tropical forests are mainly in the Congo Basin in the Congo Republic, Cameroon, Equatorial Guinea, Gabon and Congo. Only a few small isolated patches of the former forests of West Africa remain intact. Other rainforest areas that have been severely depleted are the unique forests of eastern Madagascar where most species of plants and animals are endemic.

The Indo-Malesian forests have a much more disjointed distribution owing to the island nature of the region. These forests extend from the western Ghats in India, Sri Lanka, through Assam, Myanmar, Thailand, Indo China and the Malay Peninsula to the Philippines, the Indonesian archipelago, and east as far as Fiji in the Pacific, and into the Queensland Peninsula of Australia where it reaches its southernmost limit and blends into the subtropical forests of New South Wales. The main difference between the Malesian forest and those of the rest of the tropics is the dominance of a single plant family the Dipterocarpaceae (genera *Dipterocarpus*, *Dryobalanops*, *Hopea* and *Shorea*).

Most tropical forests are over the soil types *oxisols* and *ultisols*, both of which are acid, low in organic matter content and extremely low in available plant nutrients. Most of the nutrients are in the decomposing leaves and branches on the soil surface and are rapidly recycled back into the vegetation. Ultisols are prone to erosion and to the formation of laterite consisting of iron-rich clay. One of the consequences of the poor soils is that most attempts to fell tropical forest and replace it with agriculture do not work. This can be easily seen from the abandoned areas of cattle pasture along the trans-Amazon highway or the vast areas

of unusable coarse grassland which has replaced much of the rainforests of Madagascar and Malesia, where *Imperata cylindrica* grassland prevents the recolonization by woody species.

Lowland tropical forests are renowned for their diversity of plant and animal species. Table 2 gives some statistics for the diversity of rainforest trees. It is estimated that about 50% of the world's species occur in tropical rainforests, which occupy only 7% of the land surface. This diversity and the local distribution of so many species is, in itself, a powerful argument for the preservation of tropical forests. In some areas of the Neotropical rainforest 300 tree species of over 10 cm in trunk diameter occur on a single hectare. The 100 km square Reserva Florestal Adolfo Ducke near Manaus, Brazil contains 2125 species of flowering plants in comparison to the 1500 in the entire British flora. Barro Colorado Island in Panama has 1316 species of plants in its 15.6 km^2, and the Río Palenque Science Center in Ecuador contains 1100 species in 167 hectares, and Brunei Darussalam, an area of 5767 km^2 has 4000 species of vascular plants. Table 2 shows that the non-flooded forests tend to be more diverse than flooded ones.

The diversity of plants in tropical forests enables them to sustain an enormous diversity of animals, especially insects, many of which are adapted to the canopy of a particular species of tree. Animals have adapted to the resources in the different levels of the forest. Birds and bats hunt above the canopy, and there is a vast selection of birds, fruit bats and mammals, including primates feeding in the canopy. In the middle zones there are both flying animals and animals whose habitat is the tree trunks, such as many well-disguised lizards and chameleons. At ground level, the animals vary from large mammals such as pigs, tapirs and deer to small rodents and mixed flocks of birds which follow army ant colonies feeding on the insects which the ants disturb. In Australia and New Guinea the large flightless cassowaries occupy the fruit-eating niche on the forest floor that is occupied by mammals in other tropical forests. There are many cases of different groups of animals performing the same function on the different tropical continents. A striking example is the similarity between the Neotropical toucans and the Old World hornbills.

Until relatively recently, most tropical forests were not seriously disturbed. Indigenous populations have lived in and used tropical forests for many generations, but their activities had little effect on the distribution of forest or the species composition. A few notable species became extinct in earlier times such as some of the megafauna of South America and various island species such as the dodo on Mauritius. From about 1600, as western civilization began to colonize the world and introduce many new crops, large areas of forest were cleared. Coffee and cacao plantations in Brazil, rubber in Malaysia, tea in India, sugar in the Caribbean and northeast Brazil all took their toll. However, it has been the last 50 years, as the world population has soared and tropical countries have developed, that a vast change has taken place and deforestation has been rapid.

Deforestation has occurred for many reasons, but one of the principal ones has been to provide land for increasing populations. Transmigration projects to occupy forested areas have been sponsored by the governments of Brazil and Indonesia. The need for fuel wood by poor people and for tropical timber by the developed countries has caused much deforestation, the latter particularly in tropical Asia and West Africa. Roads, hydroelectric dams, the expansion of cities, and mining activities have all taken their toll. Today just over half of the world's tropical forests have been cleared.

An assessment of the status of the world's remaining closed forests has recently been published by UNEP (Singh *et al.*, 2001). See www.na.unep.net/pub/closedforest/.

Table 3 Areas of closed forest in nine of the countries that contribute most to the world's closed forest cover. (Temperate zone forests included for comparison)

	Country size of area of closed forest (billions of hectares)	Percent of country's land area
Russia	669.6	40
Canada	368.6	37
Brazil	361.5	42
USA	236.6	25
Rep. Congo	116.2	49
China	115.5	12
Indonesia	92.7	49
Mexico	60.1	30
Peru	59.3	45

Closed forests are defined as forests where 40% or more of tree crowns are interlocked (Singh *et al.*, 2001). See Table 3 for summary.

Some of the most interesting results are that:

Of the planet's remaining closed forests, 80.6% are located in only 15 countries – Russia, Canada, Brazil, the United States, the Democratic Republic of the Congo, China, Indonesia, Mexico, Peru, Columbia, Bolivia, Venezuela, India, Australia and Papua New Guinea. Four are industrialized countries and 11 are in the developing world. Ten are in the tropics, or partly so.

Population pressures vary between countries. Overall, 88% of the world's closed forests in these 15 countries have low or non-existent population densities.

Overall, an estimated 88% of these forests have low levels of people living in and around them, giving conservation efforts a real chance of success.

Amongst the 15 key countries, Venezuela enjoys the highest level of protection, with 63% of the closed forest designated as protected. This is followed by Bolivia with 30%, Columbia 25% and Indonesia 20%. In contrast, the lowest level of protection is only 2% in Russia while the figures are 6.7% for the United States and 7.4% for Canada.

The loss of tropical forests is contributing to the global increase in atmospheric CO_2 both through the release of carbon from burning the forest and from removal of this important sink of carbon. Brazilian scientists Salati and Vose (1984) showed that deforestation in Amazonia could lead to a vast change in the rainfall pattern of the entire region, because 75% of the rainfall is recycled through evapotranspiration and only 25% flows out through the river system. The loss of tropical forest has many other implications such as the loss of species and of the potential uses to which they might be put. In addition deforestation is leading to a vast loss of the nutrients stored in the vegetation and to serious erosion in many places. Often the increase in sediment washed out to sea is having an adverse effect on marine ecosystems, especially the species-diverse coral reefs. The tropical forests of the world are being destroyed largely for short-term and unsustainable uses. One of the great challenges facing the 21st century is to halt the destruction of tropical forest, and introduce sustainable land use systems in the areas where the forest has already been destroyed.

An excellent summary of tropical rainforests can be found in Richards (1996).

Tropical Savannas

Ernesto Medina

Instituto Venezolano de Investigaciones Cient´ cas, Caracas, Venezuela

Tropical savannas are ecosystems characterized by a continuous herbaceous cover of sun loving (heliophilous), perennial bunch grasses and sedges, almost exclusively with the carbon-4 (C4) photosynthetic pathway, that show a clear seasonality related to water stress. Woody species (shrubs, trees and palms) occur in varying density depending on soil depth and water availability. Legumes are commonly found in savanna vegetation as herbaceous, shrubby and tree species; particularly in South American savannas they can

reach high specific diversity. Most shrub and tree species in tropical savannas of Western Africa, Australia, and South America are evergreen, and produce new leaves towards the end of the dry season.

Physiognomic and functionally similar systems extend into the subtropics in Africa, Australia and South America. However, at higher latitudes frost occurrence becomes an additional selecting factor. The main difference between savannas and temperate prairies is the occurrence in the latter of frost-resistant herbaceous and woody species.

Figures on the total extent of savannas are variable. Estimates range from 21 to 24 $\times 10^6$ km^2 from which about 15 $\times 10^6$ km^2 correspond to tropical latitudes. Savanna ecosystems cover large areas of the terrestrial surface of Africa (65%), Australia (60%) and South America (45%).

Savannas have been heavily modified throughout human history. The cradle of humankind is located in the African savannas (about 500 000 years ago), while human occupation is only 40 000 years old in Australia and around 15 000 years old in South America. From the very beginning human modification of savannas operated through the utilization of fire for hunting, and the domestication of herbivores. However, massive modification is relatively recent, beginning with the arrival of European settlers. Most modifications are related to the agricultural exploitation of grasslands, resulting in pronounced variations in species diversity and disruption of ecosystem functioning such as productivity and related processes of water and nutrient cycling (particularly nitrogen).

Currently savannas are burned regularly, mostly because of human influences. There is little doubt that the present extent of savannas is to a significant degree the result of human induced fires. However, the occurrence of fire probably regulated the distribution and species composition of savannas long ago, particularly in tropical South America. Due to recurrent fires, the current carbon balance of savanna areas is probably at equilibrium, organic matter accumulated during the rainy season being returned to the atmosphere during the dry season. However, precise, large-scale measurements of the carbon balance are lacking.

Most tropical savannas are comparatively humid, with annual rainfall above 800 mm, have acid, dystrophic to slightly mesotrophic soils, and are burned on an annual or biannual basis. Grasslands in the African highlands characterized by the occurrence of brown, eutrophic soils of alkaline pH are not considered here, because of their contrasting nutritional conditions.

VEGETATION AND FLORISTIC DIVERSITY IN SAVANNAS

The large-scale geographical distribution of savannas in the tropics appears to be primarily correlated with the presence of a pronounced seasonal rainfall regime, but their regional distribution pattern is more strongly influenced by local edaphic and biotic conditions. Different savanna types occupy in some cases wide and continuous areas with a relatively homogeneous climatic regime, as for example in Northern and Central South America, central and Western Africa, Southern India, and Northern Australia. On the other hand, isolated savannas occurring in small patches interspersed in large forested regions, as for example in the Amazon basin or in parts of Southeast Asia, are mainly the result of peculiar edaphic or historical situations.

Generally, the density of the ligneous component is used as a differential criterion for the definition of a particular savanna type. Thus, savanna vegetation types vary from open grasslands, where the woody component, if present, does not surpass the height of the dominant grass layer, through shrub savannas, tree savannas and savanna woodlands or forests dominated by tree species with hard, leather-textured, leaves (*sclerophyllous*).

In African savannas the herb layer shows various degrees of differentiation into tall grass savannas and low grass savannas, probably in response to the selective impact produced by the much higher density and diversity of large herbivores.

Contrary to tropical humid forest ecosystems, where the predominance of certain plant families is rather the exception, savannas are invariably dominated in their herbaceous layer by only two large families, namely the grasses (*Poaceae*) and the sedges (*Cyperaceae*). In most savannas of the world, these two families account not only for the largest number of species, but they also constitute the main biomass of the ecosystem. Third in floristic importance are the legumes (*Fabaceae*). Other important herb families are *Asteraceae*, *Rubiaceae*, *Euphorbiaceae*, *Labiatae*, *Convolvulaceae*, *Scrophulariaceae*, *Gentianaceae*, and *Sterculiaceae*.

The ligneous compartment consists of a variable number of species belonging to many families. Of these, four families are particularly important in the neotropical shrub savannas: *Dilleniaceae*, with the widespread but almost exclusive savanna treelet *Curatella americana*; Malphigiaceae, with the large genus *Byrsonima*; *Proteaceae* (*Roupala*), and *Arecaceae* (palms) with numerous genera and species. Furthermore, each savanna region of South America has an additional set of typical woody species. Examples are *Salvertia convallariodora* (Vochysiaceae) and *Hancornia speciosa* (Apocynaceae) in the central Brazilian cerrados, *Antonia ovata* (Loganiaceae) in the Northern Brazilian Rio Branco savannas, and *Heteropteris laurifolia* (Malphigicaeae) in the Bolivian savannas. In Australian savannas, species of the genus *Eucalyptus* dominate the ligneous compartment in shrub and tree savannas, while in Africa the legumes genera *Brachystegia*, *Julbernardia*, *Burkea*, *Colophospermum*, and *Acacia* dominate the ligneous stratum of the largest tracts of savanna ecosystems.

LIFE FORMS AND THEIR FUNCTIONAL SIGNIFICANCE

Well-developed savanna ecosystems contain almost the entire spectrum of life forms in the classical sense of Raunkiaer (Danish ecologist who classified higher plants according to the protection of their growing points against environmental stress), such as phanerophytes, chamaephytes, hemicryptophytes, geophytes, and therophytes. However, dominant life forms in savannas are those of perennial species and within them two groups contain the largest number of species: the herbaceous graminoid and broad-leaved species and the sub-ligneous and ligneous hemicryptophytes.

The graminoid life form presents two major growth forms, i.e., the tussock or bunch grass growth form, and the solitary growth form. The former consists of a dense tuft of up to one meter or more in diameter of perennial grasses or sedges, all arising from a common rootstock. This is by far the predominant growth form in the herbaceous layer of most savannas, as for example *Trachypogon plumosus* (Poaceae) or *Scleria cyperina* (Cyperaceae) in many Neotropical savannas. The solitary growth form is more commonly found in annual grass or sedge species, although some perennial grasses may also exhibit this feature.

Tree and herbaceous components in savannas exploit water and nutrient resources from different soil layers. In neotropical savannas, trees appear not to be limited by water supply, because they are able to exploit soil layers influenced by the water table, while grasses show strong seasonal variations in water potential and a large degree of osmotic adjustment. However, both density and height of the tree-root layer are positively related to soil water availability during the dry season. The establishment of tree seedlings depends on the occurrence of wet years, that help them to withstand root competition from perennial grasses during early stages of growth.

Soil fertility also influences actual tree/grass ratios, as shown in the physiognomic sequence from savanna woodland to the open shrubby grasslands in central Brazil. The reduction in the number of tree stems and species per hectare (ha) observed in this sequence may be attributed both to a reduction in nutrient availability and increased aluminum saturation of the soil exchange complex. However, these nutritional gradients might be the result and not the cause of vegetation composition, especially when only the chemical composition of the upper soil layers is taken into account.

Differences in density of the tree layer may also result from variations in frequency and intensity of the fire regime. Fire suppression for more than 20 years in several savanna sites in different continents led to significant increases in diversity of both tree and herbaceous layers, and the immigration of tree species from surrounding forests.

Resistance of savanna ecosystems to environmental stresses such as drought, herbivory, and fire is associated with the development of underground organs. Most savanna ecosystems are characterized by large below-ground/above-ground ratios. Allocation of biomass to underground organs conserves carbon, energy and nutrients allowing the recovery of grass, shrub, and tree layers after regular, or even catastrophic events of drought, herbivory, and fire.

BIODIVERSITY AND THE EFFICIENCY OF RESOURCE UTILIZATION

Photosynthetic Types and Water-use Ef ciency

Combinations of rainfall and soils texture regulate moisture availability, determining gradients from wet to dry savanna environments. Savanna ecosystems extend from semi-arid regions to seasonally flooded areas because of the combination of high rainfall and heavy soils. Savannas are accordingly classified as *dry*, *intermediate*, *wet* and *swampy*, or *slightly seasonal*, *seasonal* and *hyperseasonal* (Table 1). The graminoid layer of the different savanna types falls into a well-separated taxonomic and physiologic pattern.

A few tribes of grasses have strong dominance in savanna environments: Panicae (e.g., *Axonopus*, *Digitaria*, *Panicum*, *Paspalum*, *Setaria*), Andropogonae (*Andropogon*, *Elionurus*, *Gymnopogon*, *Heteropogon*, *Hyparrhenia*, *Imperata*,

Table 1 Savanna types and predominant grass groups (based on Sarmiento, 1984, and Johnson and Tothill, 1985). Moisture regimes derive from a combination of rainfall, potential evaporation and soil texture

Moisture regime and soil texture	Savanna type	Dominant grass tribes
Wet (1000- 2000 mm), medium to heavy	Swamp grasslands Hyperseasonal Savannas	Panicoid- Oryzoid Panicoid- Andropogonoid
Seasonal (500- 2000 mm), medium to sandy	Savanna woodland Savanna parkland Savanna grassland	Panicoid- Andropogonoid
Dry (250- 800 mm), heavy to sandy	Low tree and shrub grasslands	Eragrostoid- Aristidoid- Chloridoid

Themeda, *Trachypogon*), Aristideae (*Aristida*), *Eragrostidae* (*Eragrostis*, *Dactyloctenium*, *Eleusine*) and Chlorideae (*Chloris*, *Microchloa*). The Andropogonae dominate the core of the savanna ecosystems, while the semi-arid savannas are dominated by representatives of the Chloridoid, Aristidoid and Eragrostoid tribes. The proportion of Panicoid increases strongly towards wetter savannas and the Oryzoids dominate in the swampy savannas, or esteros of South America. However, the Panicoid have the largest ecological range, and this tribe is heavily represented in all seasonal and hyperseasonal savannas.

The variation in dominance of different grass tribes from dry savannas to wet and swampy, hyperseasonal savannas, is associated to the photosynthetic metabolism. Carbon-4 (C4) grasses dominate the herbaceous layer of semi-arid and seasonal humid savannas, while in swampy savannas frequently C3 grasses reach the absolute dominance level, or share the niche with flood-tolerant C4 grasses (*see* **C_3 and C_4 Photosynthesis**, Volume 2).

Within the C4 photosynthetic type further subdivisions can be made according to the first stable acid synthesized after carbon dioxide (CO_2) fixation in the mesophyll, as malate formers, and aspartate formers. Aspartate formers predominate in dry savannas, while the malate former is the dominant photosynthetic type in humid savannas growing on dystrophic soils. This distribution is probably associated with water use efficiency, higher in C4 than in C3 grasses, and with higher nutritional requirements of C3 species and of the aspartate formers among the C4 species.

The predominance of the C4 pathway of photosynthesis within the single most important family in savanna environments suggests that the higher water use efficiency and productivity associated with this photosynthetic pathway provides competitive advantage in a hot, seasonally dry climate. Similar distribution patterns of photosynthetic pathways can be detected within the Cyperaceae (C4 types in seasonal and dry savannas, C3 types predominating in hyperseasonal savannas). However, among the dicotyledonous families, the C3 photosynthetic type predominates, C4 species being found only within the genera *Euphorbia* (Euphorbiaceae) and *Pectis* (Asteraceae). The Leguminosae, the most characteristic plant group of tropical savannas beside the grasses, belong homogeneously to the C3 photosynthetic type. When grown under optimal conditions, legume species always have lower photosynthetic capacity than C4 grasses. The variety and frequency of legumes shows that water stress is not the only determinant driving force structuring the herbaceous layer of savanna ecosystems.

Phenological Spread as a Means of Resource Partition

According to their periods of flowering, exponential growth, and maximum biomass accumulation, savanna grasses can be separated into groups of precocious, early, intermediate, and late growing species. The periods of exponential growth of early, intermediate, and late species do not overlap, and intermediate and late growers accumulate larger above-ground biomass than early growers do. The below-ground to above-ground biomass ratios decrease from the early growers, to intermediate, and late growers. Early growers have higher water use efficiency than late growers and are able to exploit the early pulse of nutrient supply resulting from the mineralization of organic matter at the beginning of the rainy season. However, they produce less organic matter than the late growers. Phenological spread has also implications for the variability of the grass layer in tropical savanna. The full set of phenological behaviors can be found in humid tropical savannas with relatively short dry seasons. In this vegetation the delay in the onset of rain results in decreasing production of the early growers, while a shorter duration of the rainy season affects production and reproduction of the late species.

Physiological Differentiation in Nutrient-poor Soils

Most neotropical seasonal savannas are dystrophic or hyperdystrophic, as characterized by a sum of exchangeable bases ranging from 1–5 and less than 5 meq per 100 g soil, respectively. Therefore, the herbaceous species are expected to be very sensitive to changes in nutrient availability, and have lower nutritional requirements for normal growth than species from grassland on eutrophic soils.

The nutritional factor may contribute to the grasses-sedges dominance observed in all savanna regions of the world, because in general these families have lower nutritional requirements than dicots, particularly the Leguminosae. In natural seasonal savannas in Venezuela, legumes are deficient in phosphorus (P) and potassium (K), while nitrogen (N) reaches similar values to those expected from cultivated forage legumes. By contrast, nutritional levels of the above-ground biomass of grasses at the peak of their development are only slightly below the level expected for cultivated forage grasses. Fertilization experiments conducted in savanna areas of Africa, Australia and South America show that additions of nitrogen, or nitrogen and phosphorus together, promote organic matter production of natural grass swards. Legume growth, on the other hand, is strongly stimulated by increases of the phosphorus supply, or amendments of the soil pH through the addition of calcium carbonate ($CaCO_3$). Higher phosphorus uptake increases growth because of improved photosynthesis and nodulation. Patches of higher pH, lower phosphorus fixation after organic matter mineralization, and a higher sum of bases favor legumes over grasses and sedges in the herbaceous layer. Nutrient patches, therefore, account for much of the diversity observed in different savannas.

Photosynthetic groups within the Poaceae show differences in nutrient requirements. Aspartate-former species

of the Andropogonae are favored against malate-formers by increased nitrogen availability, a response consistent with the hypothesis that aspartate formers have relatively higher nutritional requirements. This may also explain the widespread dominance of malate formers in seasonal savannas with dystrophic soils.

BIOLOGICAL TRAITS REGULATING NUTRIENT AVAILABILITY

Grass- tree Interactions

Trees and shrubs generally exploit deeper soil layers compared to grasses and other herbaceous species. Scattered trees and shrubs constitute areas of nutrient enrichment, at least in the upper soil layers. This may account partially for the differences in floristic composition, density, and productivity of the vegetation underneath woody perennials in several savanna areas. The presence of trees within a grassland also results in changes in light conditions, temperature, and evapotranspiration, factors powerful enough to explain the variations observed in the herbaceous vegetation. The richer nutrient environment underneath the tree components may allow the establishment of other woody species with higher nutrient requirements leading to the development of tree groups. In South American savannas, deciduous trees, presumably more nutrient demanding, are restricted to forest groves, while less demanding evergreen trees are found scattered within the grass layer of the savannas. However, this distribution may also result from differences in fire tolerance.

Mound-building Termites and Leaf-cutting Ants

Mound-building termites are common in all savanna regions of the world, although they are most significant in Northern Australia and Western Africa. During mound building, termites modify the physicochemical characteristics of the soils, in texture by selecting finer particles more appropriate for mound building, and in nutrient content because of the mixing with food residues. Termite species are efficient foragers of organic debris (nearly $1000\,kg\,ha^{-1}\,a^{-1}$), therefore they can deprive the surroundings of organic carbon input and the nutrients contained in the plant litter. In Australia, *Amitermes* and *Nasutitermes* mineralize approximately $250\,kg\,ha^{-1}\,a^{-1}$ of organic matter, and this may be an important contribution to nutrient recycling in nutrient-poor soils.

Leaf-cutting ants play a significant role in nutrient cycling in some Brazilian savannas. Burying large amounts of nutrient enriched litter may provide a source of nutrients for deep-rooted woody plants. This foraging activity sequesters significant amounts of nutrients from aboveground, avoiding their volatilization through fire at the end of the rainy season.

Rhizospheric Associations and Mutualistic Symbiosis

The predominance of soils with intrinsic low nutrient availability constitute the ecological background for the evolution of several symbiotic or quasi-symbiotic mutualistic associations in tropical savannas: (a) legume–*Rhizobia* symbiosis mediating nitrogen-fixation; (b) mycorrhizal symbiosis, improving phosphorus and water uptake through expanded soil exploration, and (c) rhizospheric microflora, enhancing nutrient availability through solubilization, or direct nitrogen fixation.

A large number of savanna leguminous species, particularly within the Fabaceae, are nodulated in the field. The nitrogen fixation activity of these nodules, however, is frequently limited by widespread phosphorus deficiency of savanna soils.

Phosphorus requirements of native legumes under natural conditions can be met through the formation of endo-mycorrhizal symbiosis. Savanna legumes develop frequently tripartite symbiosis with native *Rhizobia* strains, and mycorrhizogenous fungi under natural conditions. Enhancement of phosphorus uptake through mycorrhiza increases nodulation by native or introduced Rhizobia and improves nitrogen-fixation.

Rhizospheric associations with microorganisms of the type of *Azospirillum* are widespread in tropical savannas and they seem to be responsible for a significant amount of nitrogen supply to savanna soils.

Fixation of atmospheric nitrogen in savannas is also mediated by blue-green algae. In many savanna sites algal mats develop at the soil surface during the rainy season, with rates of nitrogen-fixation amounting to several $kg\,ha^{-1}$. Nitrogen flow into savanna soils mediated by algae and rhizospheric organisms seems to be large enough to offset partially the nitrogen losses caused by annual grass burning.

SUMMARIZING REMARKS

The following characteristics can be uniquely associated with tropical savanna vegetation, either as separate categories or as integrated properties:

1. Grasses with the C4 photosynthetic pathway dominate both the physiognomy and the production of organic matter in all seasonal savannas of the world. Within the grasses, an additional differentiation is observed regarding the dominance of aspartate formers in drier savannas, and malate formers in humid, seasonal savannas with soils of low nutrient availability. The relationships between photosynthetic pathways and nutritional requirements have not been experimentally established, but long-term field experiments show clearly that fertilization with nitrogen favors the production of organic

matter of aspartate-formers and reduces the competitiveness of malate formers in grass swards where both types coexist.

2. The typical savanna structure includes the coexistence of trees and grasses. The competition for resource acquisition, particularly water, between these two contrasting life forms is reduced by the differences in root distribution in the soil. Establishment of tree seedlings, however, might be limited to wet years, to allow the root of the tree seedling to cross the soil layer dominated by grass roots.
3. All savannas are characterized by the predominance of perennial species with strong development of underground organs, the root/shoot ratio being generally above one. This biomass allocation pattern is very well related to the tolerance of savanna vegetation to stresses such as drought, fire, and herbivory.
4. Diversity of developmental patterns of savanna species and the differentiation in nutritional requirements allow segregation in space and time of the demand for resources. Grasses in general appear to be more dependent on nitrogen supply, while legumes, and other dicots, are more limited by phosphorus supply.
5. Savanna environments being nutrient limited, emphasize the significance of symbiosis for nutrient acquisition. Legume–rhizobium–mycorrhizal symbioses, and rhizospheric associations with free-living nitrogen fixing bacteria, are very widespread, but their actual activity in nutrient supply at the ecosystem level has been measured only in a few cases. The activity of root symbioses together with the ubiquitous presence of blue-green algae, provide the basis for stabilizing nutrient budgets in savannas, particularly the recovery of nitrogen losses induced by extensive burning.

Tucker, Jim

(1946–)

Compton James Tucker III, born 15 April, 1946 in Carlsbad, NM, received his BS in Biology (1969), MS (1973) and PhD (1975) from the College of Forestry of the University of Colorado, Ft. Collins. He has been affiliated with NASA's Goddard Space Flight Center in Maryland since 1975, first as a National Academy of Sciences post-doctoral fellow, and since 1977, as a physical scientist. His awards include the Exceptional Scientific Achievement Award (1986), Exceptional Scientific Achievement Medal (1987) and William Nordberg Memorial Award for Earth Sciences (1995), all of the National Aeronautics and Space Administration; the Henry Shaw Medal (1992) of the Missouri Botanical Garden, the National Air and Space Museum Trophy (1993), and the William T. Pecora Award of the US Geological Survey. He is also the first American co-recipient (with Mary L Cleave) of the Mongolian Friendship Medal, and a Goddard Senior Fellow.

Dr Tucker is a key pioneer in the use of satellite observations to study vegetation dynamics and its changes through time. He led the development and application of satellite observations of the normalized difference vegetation index (NDVI) for land surface studies. Because of the intrinsic difference in spectral properties of green leaves and of soils, the NDVI, expressed as the difference divided by the sum of the near infrared and visible reflectances, is a good correlate of photosynthetic activity of the land surface. The utility of the NDVI was first demonstrated by Dr Tucker with ground-based data collection and analyses using spectrometers and hand-held radiometers. He is instrumental in processing visible and near-infrared reflectance data from the advanced very high resolution radiometer (AVHRR) on board the polar-orbiting weather satellites (the NOAA-n series), and the production of the first continental and global observations of photosynthetic activity. These large-scale observations of the terrestrial biosphere were remarkable not only because they revealed a coherent structure over scales much larger than would be expected from the heterogeneity of the landscape, but also because the satellite instruments were not specifically designed for biospheric observations. The global multi-temporal observations of the NDVI have been used to classify and estimate areal extents of vegetation types, to study the photosynthetic drawdown of carbon dioxide (CO_2) from the atmosphere, to monitor the expansion and contraction of deserts and other xeromorphic vegetation, and to detect changes in the growing season at high-latitudes. It is now a routine observation of the terrestrial biosphere.

In addition to the AVHRR, Dr Tucker has also spearheaded the use of Landsat satellite data for studying land vegetation dynamics including deforestation, habitat fragmentation, and desert boundary determination.

By the 1990s, NDVI observations of the terrestrial biosphere had become routine, and widely used in large-scale studies of the terrestrial biosphere and its changes. These observations are no longer derived only from the AVHRR on weather satellites, but also from satellite instruments designed for biospheric observations. These include the sea-viewing wide field of view sensor (SeaWIFS) on board

the Seastar spacecraft launched in August 1997 and the moderate-resolution imaging spectroradiometer (MODIS) instrument on board Terra satellite launched in December 1999.

Tundra

Philip A Wookey
Uppsala University, Uppsala, Sweden

Lying beyond the poleward or altitudinal limit for the growth of trees, tundra ecosystems exhibit much greater diversity in community type, soil characteristics, geomorphology and topography than is commonly perceived. They also occupy a broad environmental space (range of climatic conditions, expressed in terms of temperature and precipitation, under which tundra systems develop), from extreme polar deserts of, for example, the Russian Arctic archipelagos, northern Canada and Greenland to the closed-canopy tundra of the Low Arctic, and the alpine tundra of mountain regions. Although net primary productivity (NPP) is generally low, there is a very large range of mean values (from 1–375 g m^{-2} $year^{-1}$ total above- and below-ground NPP for high arctic polar deserts and low arctic low shrub tundra, respectively), again reflecting the broad heterogeneity of tundra. In spite of low NPP, tundra systems are key feeding and breeding grounds for large populations of grazing mammals (e.g., reindeer in Eurasia and caribou in North America and Greenland, muskoxen, lemmings and voles) and birds (e.g., snow and barnacle geese) together with their associated predators and scavengers (e.g., wolves, foxes and raptors).

Tundra ecosystems are of global biogeochemical significance since, on balance, they have been removing carbon dioxide (CO_2) from the atmosphere during the last 10 000 years and storing it as soil organic matter (although recent research suggests that this situation may now be changing), while releasing methane (CH_4). They also influence the global energy budget by reflecting significantly more solar energy back to outer space than the boreal forests to the south. Tundra is thus coupled to the global climate system and also to atmospheric composition (CO_2 and CH_4 concentrations, in particular). Ecosystem responses to environmental change in tundra therefore have potential to feed back on further change through alterations in net fluxes of radiatively forcing (greenhouse) gases or through changes in surface roughness and reflectance (albedo).

General circulation models (GCMs) suggest that climatic change in Arctic tundra regions could be of greater magnitude than the average predicted changes for the Earth as a whole. Many ecologists also hypothesize that any given change in temperature will have a greater biological impact in cold systems than in warmer ones, due to the disproportionate impact on heat sum (degree days). It has also been suggested that, since some tundra species may be surviving at or near the geographical limits of their range, they may therefore be particularly sensitive to an improvement or deterioration in environmental conditions. Climatic changes, together with other key facets of global environmental change (rising atmospheric CO_2 concentrations, increasing deposition of airborne nitrogen (N)-containing pollutants, and possible increased fluxes of ultraviolet (UV)-B radiation to the surface) all have the potential, both singly and in combination, to alter the structure and functioning of tundra systems.

BACKGROUND

The term *tundra* is derived from the Sámi word *tundar* (in Finnish *tunturi*), which refers to a treeless hill, or elevated ground, in northern Fennoscandia. The high latitude tundras (*Arctic tundra*) of the Northern Hemisphere are by far the largest in the tundra biome, covering around 5.6 million km^2. At lower latitudes, tundra ecosystems are found at higher elevations associated with mountain regions (*alpine tundra*) and in equatorial regions they occur above the tree line at altitudes higher than 4000 m. Alpine tundra occurs across a very great range of latitudes and geological settings and their environments (photoperiod, net receipt of solar radiation, diurnal temperature ranges, length of growing season) are correspondingly diverse. A notable feature of alpine tundra is that it is often geographically highly fragmented and occurs as 'islands' separated by warmer ecosystems of lower elevation. Topographic controls often result in better-drained soils in alpine tundra than in arctic systems, and alpine tundra often also lacks underlying permafrost. Tundra ecosystems are not, therefore, homogeneous (Figure 1).

For arctic tundra, several distinct vegetation zones have been recognized, with forest-tundra representing the (often diffuse) transition between the boreal forest (*taiga*) and tundra biomes. Bliss and Matveyeva (1992) have sought to unify the North American and Russian classification schemes. With increasing climatic severity, forest–tundra grades into several contrasting Low Arctic systems including *shrub tundras* with an open canopy of low shrubs some 40–60 cm high (comprising species such as dwarf birch, *Betula nana*, shrub willows and alders) and an almost complete ground cover of dwarf heath shrubs, abundant foliose lichens (notably *Cladonia* spp., *Cladina* spp., and *Cetraria* spp.), mosses, grasses and forbs. Such Low Arctic shrub

communities represent the most productive tundra types and they occur in favorable environments just north of the tree line. At the other end of the spectrum, and found in areas with a thaw period as short as six weeks per year with average temperatures for the warmest month not exceeding 2–6 °C, are the High Arctic polar deserts and semi-deserts with their incomplete and diminutive vegetation cover of cushion or mat-forming plants (e.g., mountain avens, *Dryas octopetala*, and purple saxifrage, *Saxifraga oppositifolia*) creeping dwarf shrubs (e.g., *Salix arctica*), rosette-forming plants, mosses, graminoids (grasses and sedges), lichen and cyanobacterial crusts. The extreme High Arctic ecosystems have very low precipitation totals (often with a pronounced summer peak) and winter snow cover is, paradoxically, often thin (compared with much deeper snow in many Low Arctic tundras farther south): surface drying during the thaw period can create significant water stress here, particularly if substrates are freely draining.

Although rates of NPP are generally low in tundra ecosystems compared with the other major biomes, the reservoirs of organic material in tundra soils are disproportionately high, especially in poorly drained regions of the Arctic tundra (Figure 2). Tundra soils worldwide are estimated to contain between 121–191 Gt of carbon (C) (ca. 11–14% of the global total soil carbon reservoir, although tundra systems cover ca. 5–6% of the land area).

Figure 2 Arctic tundra, North Slope of Alaska (68 °N). The picture is taken in the foothills of the Brooks Range and shows tussock tundra, where hare's tail cotton sedge (*Eriophorum vaginatum*) and dwarf birch (*Betula nana*) are important elements in the vegetation community. The region is underlain by continuous permafrost and the soils are poorly drained. The combination of cold and wet conditions restricts decomposition processes so that soil organic matter contents are high. The mean temperature of the warmest month is around 10 °C (July)

GLOBAL ENVIRONMENTAL CHANGE AND TUNDRA

Tundra systems have been receiving considerable attention from researchers interested in the potential impacts of global environmental change. The output from GCMs points to a greater than average warming at high northern latitudes, especially during the winter months. These predictions, together with the potential increases in UV-B fluxes to the surface (associated with the already observed springtime depletion of stratospheric ozone at high latitudes) and the increased deposition of, in particular, nitrogen(N)-containing pollutant compounds originating from industrial regions, are all facets of global environmental change that have implications for the structure and functioning of tundra systems. The scenarios of environmental change in tundra regions are complex and there is considerable uncertainty regarding the magnitude and even, for some parameters (e.g., precipitation quantities and form – rain or snow) the direction of change. The key scientific issues, however, are introduced through reference to major research topics and case studies. Tundra ecosystems are also directly impacted by mineral and fossil fuel extraction, transport infrastructure, animal husbandry (e.g., reindeer herding) and tourism: the effects of global environmental change must be viewed within the context of these local and regional disturbances, which under some circumstances will strongly override, or interact with, the impacts of global change (see Crawford (1997) and articles therein).

Experiments with Ecosystems

In tundra it is possible to conduct experiments in plots of manageable size (a few square meters or even smaller) in which the environment can be manipulated to simulate the impacts of global environmental change on well-defined community types. Some notable experiments that have sought to understand the potential responsiveness and resilience of tundra plant species, vegetation communities and soils to climatic warming include studies at Toolik Lake on the North Slope of Alaska (Chapin *et al.*, 1995), the International Tundra Experiment (ITEX) (Henry and Molau, 1997; Arft *et al.*, 1999), and the comparative studies on European Arctic (Swedish Lapland and northwest Spitzbergen) ecosystems by Malcolm Press and colleagues (see Press *et al.* (1998) and references therein). In all of these examples, air (and to a lesser extent soil) temperature during the thaw period has been manipulated quite simply using either plastic greenhouses or hexagonal open-topped chambers to give a warming of 1–3.5 °C above ambient temperatures. The work at Toolik was initiated in 1981, and provides the longest time series, while the ITEX and other European Arctic studies began in the early 1990s but cover a broader range of arctic and alpine sites.

These experiments have together highlighted some key aspects of tundra response to warming: (i) plant species respond individualistically to warming (and, as shown in the Toolik experiments, fertilizer additions and shading treatments), making generalizations about growth form (e.g., deciduous or evergreen dwarf shrubs, forbs or graminoids) difficult, and extrapolating conclusions from one tundra community type to another potentially misleading; and (ii) responses to warming generally decline over time as some other resource (other than thermal energy) becomes limiting (e.g., soil nutrients). The Toolik studies, in addition, indicate that the individualistic responses of plant species to alterations in temperature (and also nutrient availability) generally cancel one another out and result in little overall change in community NPP and biomass (Terry Chapin and colleagues suggest, accordingly, that the system is buffered against change: Chapin *et al.*, 1995). How general this phenomenon is throughout the tundra biome is hard to judge without comparable data from other systems, but it does suggest a degree of resilience to environmental variability, at least in these Low Arctic systems with their complete vegetation cover (such observations were also supported by the work in Swedish Lapland).

Experiments being conducted by the ITEX team and in the European study, although focused principally on individual plant species of broad circumpolar arctic and alpine distribution, have allowed geographical comparisons to be made, and have also illustrated the detailed basis of individual species responses to warming. What can be concluded at this stage from the work is that (i) plant reproductive development is accelerated and seed output is increased markedly with warming, especially in the High Arctic; and (ii) vegetative growth at most sites was increased in the early years of the experiment, but this response declines with time and may not be sustained in the longer term (due, perhaps, to nutrient limitations). For many vascular plant species in Arctic Tundra (most of which are perennials) the ability to respond rapidly to warming, in terms of reproductive development, is important because flowering, pollination and seed-set must be completed rapidly before the onset of winter. Vegetative growth, by contrast, can be spread over many years and may be as much constrained by nutrient availability as growing-season duration and temperature. Increased success of seed set in response to warming may have particularly profound implications for tundra ecosystems in the High Arctic, where large areas of incomplete vegetation cover may provide opportunities for seedling establishment and colonization of bare ground. In one experimental study in a polar semi-desert community in northwestern Spitzbergen, the author and colleagues (1995, cited in Press *et al.*, 1998) observed a seven-fold increase in the output of viable seed of mountain avens (*D. octopetala*) in response to a warming of 3.5 °C above ambient (5.4 °C) summer temperatures. Whether such increased production

of viable seed could actually translate into colonization of bare ground in the High Arctic will, however, depend on the availability of suitable microsites (so-called *safe sites*) for seedling germination and establishment, and suitable moisture, nutrient and temperature regimes for plant survival in the longer term. A rapid greening of High Arctic tundra areas in response to global warming is possible, although restricted nutrient availability may, again, play a key role in constraining this process.

Experiments designed to assess the impacts of increased fluxes of UV-B radiation (Lars Olof Björn and colleagues, Chapter 11 in Woodin and Marquiss, 1997), and rising atmospheric CO_2 concentrations (Oechel *et al.*, 1994; Körner *et al.*, 1997) on tundra have generally been limited to locations with good infrastructure and electrical power supplies (e.g., the Abisko area in Swedish Lapland, Toolik Lake field station in Alaska and Furka Pass in Switzerland). For elevated CO_2 concentrations, there are consistent indications that plants rapidly acclimate and rates of community NPP down-regulate to levels comparable with plants growing at ambient CO_2 concentrations: Such homeostatic adjustment is thought to reflect limitations in sink strength for photosynthates caused by nutrient limitations to plant growth, and has been seen in Alaskan tussock tundra by Walter Oechel and colleagues (Oechel and colleagues, Chapter 12 in Woodin and Marquiss, 1997) and in an alpine grassland in Switzerland by Christian Körner's research group (Körner *et al.*, 1997). In the sense that mineral nutrients may play a key role in modulating tundra responses to elevated CO_2 concentrations, there are parallels with the nutrient limitations to sustained temperature responsiveness. For UV impacts, it is much more difficult, at this stage, to gain a clear picture of potential ecosystem responses because measured effects depend greatly on the duration of the study (for UV-B they are often cumulative, and therefore potentially more serious for perennial and evergreen plant species than for annuals and deciduous species) and they are also species-specific. Plant responses to changing CO_2 concentrations and UV-B fluxes can also, of course, have knock-on effects at other trophic levels: changes in plant tissue chemistry and physical structure in response to these factors could, for example, influence decomposition processes (and hence nutrient recycling) and patterns of both vertebrate (e.g., caribou, reindeer, geese, lemmings and microtines in Arctic tundra regions) (Figure 3) and invertebrate herbivory (e.g., by aphids or woolly bear caterpillars). It is too early to make reliable predictions regarding the significance of these indirect effects for tundra ecosystems.

Alterations in timing of plant growth and flowering patterns in response to all facets of global environmental change in tundra could also have repercussions at other trophic levels: the activities of pollinators and herbivores may be particularly sensitive to these changes in tundra ecosystems due to the highly seasonal environments and short growing seasons. In one experimental study on Spitsbergen, for example, Andy Strathdee and colleagues noted that artificial warming (of 2.8 °C above ambient temperature) produced a dramatic 11-fold increase in the egg density of a sap-sucking aphid (*Acyrthosiphon svalbardicum*) on the host plant *D. octopetala*, partly because the aphid has a flexible life cycle and was able to complete three sexual generations instead of two in response to the additional 215 degrees days of thermal energy produced in the warming treatment (Bale and colleagues, Chapter 6 in Woodin and Marquiss, 1997).

Figure 3 Tundra ecosystems are important feeding and breeding grounds for both mammalian and avian herbivores. Here, a barnacle goose (*Branta leucopsis*) sits on the nest on Storholmen Island, Kongsfjord, Spitsbergen. The small island provides protection from the arctic foxes (*Alopex lagopus*) which exert a severe impact upon breeding groups on the nearby Br gger Peninsula. The Spitsbergen barnacle geese over-winter in the British Isles

In general much more work is needed to improve our ability to predict the implications of global environmental change on tundra ecosystems at all trophic levels. Experimental studies to date have focused principally on net primary producers and on single facets of environmental change or simple combinations. Clearly, single environmental factors do not change in isolation, and thus ecosystem ecologists need to consider more complex interactions and scenarios of change. Additionally, the time-scales of system response (Figure 4) are of key significance and short-term studies have only limited potential to improve our predictive ability.

Tundra Carbon Fluxes and Links with Global Biogeochemistry

Carbon Dioxide

On balance, tundra soils have been a net sink for carbon (as soil organic matter) during at least the Holocene (the post-glacial epoch covering the last 10 000 years), capturing carbon at a rate of between 0.1 and 0.3 Gt C year^{-1}.

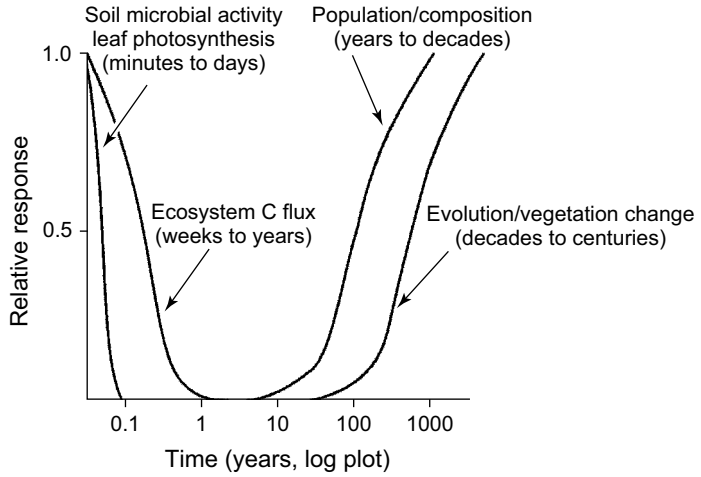

Figure 4 Hypothetical relative response times for adjustment to new atmospheric CO_2 concentrations and climatic change, for changes at the level of leaf photosynthesis and soil microbial activity, ecosystem net CO_2 ux, population structure, community composition, vegetation and evolution. (Reprinted from Oechel and Vourlitis, 1994 with permission from Elsevier Science and from the authors)

The combination of waterlogging (in many areas drainage is impeded by the presence of permafrost beneath the seasonally thawed active layer), low temperatures and poor litter quality reduces the activity of decomposer organisms in soils and has resulted in the accumulation of poorly decomposed peaty organic material, particularly in tundra wetlands and mires. Carbon accumulates when rates of NPP exceed rates of decomposition, and this pattern has been a feature of ecosystem development in wetter tundra areas. One hypothesis that was advanced by Dwight Billings and colleagues (Billings *et al.*, 1982), early in the debate on global environmental change and ecosystem carbon balances, was that decomposition in cold, wet and largely anaerobic soils would be markedly responsive to an increase in temperature and/or a decrease in the depth of the water table (drying). Warmer and drier conditions should favor more rapid metabolism in the decomposer community (see Oechel and colleagues, Chapter 12 in Woodin and Marquiss, 1997). Since decomposition processes release CO_2 back to the atmosphere, it was hypothesized that climate warming could result in many tundra and boreal ecosystems switching from being a net sink for atmospheric CO_2 to being a source, thus contributing, as a positive feedback effect, to the anthropogenic increases in atmospheric CO_2 concentrations, and thereby to further global warming.

This topic remains of key interest but there is considerable controversy, still, regarding (i) the timescales over which changes in the direction of CO_2 flux can be sustained; (ii) the actual magnitudes of contemporary tundra soil carbon reservoirs; (iii) the geographical extent of regions currently emitting carbon; (iv) the potential influence of elevated atmospheric CO_2 concentrations themselves on ecosystem processes controlling carbon fluxes; and (v) even the methodologies used to measure net fluxes. Major research work casting light on this problem has been undertaken by Walter Oechel and colleagues, and field measurement campaigns of carbon flux (particularly on the North Slope region of Alaska) have revealed significant net losses of carbon from tundra to the atmosphere in recent years. In 1993 Oechel and his associates reported rates of carbon loss amounting to 156 and $34\,g\,C\,m^{-2}\,year^{-1}$ for tussock tundra (Figure 2) and wet coastal tundra, respectively, based on measurements during the thaw period, but suggested that losses could be even greater due to continuing soil respiration in the autumn and early winter in unfrozen soils beneath the insulation provided by a snow-pack (Oechel *et al.*, 1993). Subsequent winter CO_2 flux measurements, both in Arctic and alpine tundra regions, have confirmed the importance of continuing soil respiration, even beneath the snow, which cannot be ignored in tundra carbon budgeting. Oechel *et al.* (1993) hypothesized that the cause of the switch from sink to source of CO_2 on the North Slope may relate to a regional warming (of $2-4\,^{\circ}C$) over the last few decades, resulting in increased evapotranspiration and surface drying of soils: such drying could increase penetration of oxygen into the soil profile and accelerate aerobic metabolic activity in the decomposer community.

The debate on feedbacks between climate change and tundra carbon fluxes again illustrates the importance of time-scales and geographical coverage. Several lines of evidence suggest that substantial net losses of carbon from tundra ecosystems to the atmosphere as a result of warming and drying may be transitory (see Figure 5): with increased carbon loss there should, in the medium to longer term (years to decades) be an associated increase in the rate of mineral nutrient (e.g., nitrogen and phosphorous) release through the process of mineralization (although this simple

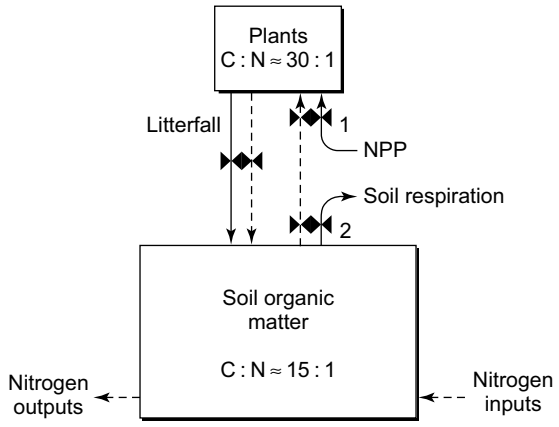

Figure 5 A conceptual model (Shaver *et al.*, 1992) of carbon/nutrient interactions in terrestrial ecosystems, using carbon and nitrogen as an example. There are two major pools of organic matter in the ecosystem (plants and soil organic material). Carbon uxes into and out of these pools are indicated by solid lines and nitrogen uxes by dashed lines. Bow ties represent links between the carbon and nitrogen uxes. Bow tie no. 1 implies that net carbon uptake by plants (NPP) is constrained by the ability of the plant to take up nitrogen, and vice versa. The suggestion made by Shaver *et al.* (1992) is that in nutrient-limited ecosystems such as tundra, the great majority of plant nitrogen supply comes from decomposition (mineralization) of soil organic matter, and that nitrogen mineralization is linked with losses of carbon due to soil respiration (bow tie no. 2). The overall carbon balance of the system is largely determined, therefore, by carbon gains associated with nitrogen uptake and losses associated with nitrogen release. In an environmental change scenario, therefore, any factors in uencing the uxes of nitrogen or carbon (e.g., changes in soil temperature or moisture regimes, atmospheric CO_2 concentrations and temperature, deposition of airborne nitrogen-containing compounds) can have implications for net carbon balance. (Reprinted from Shaver *et al.*, 1992, with permission from the authors)

linkage has not been demonstrated experimentally) (*see* **Nitrogen Mineralization**, Volume 2); in a system where such nutrients are limiting for the rate of photosynthesis, this increased availability to plants should stimulate carbon fixation and thus NPP; such responses could bring the system back from being a temporary source to a sink for carbon, as hypothesized by Shaver *et al.* (1992). Evidence in support of this can be found in the paleoecological record of organic matter accumulation rates, while ecosystem modeling activities (see McKane *et al.*, 1997), simulating controls on carbon and nitrogen fluxes in tussock tundra, also suggest that large losses of carbon may be transitory in nature. Indeed, an update by Oechel *et al.* (2000) reported that continued climate warming and soil drying in the North Slope region of Alaska has diminished the strength of CO_2 emissions (compared with those reported in 1993), although they note that the systems studied currently remain a net source of CO_2 to the atmosphere. Further field flux measurements in contrasting ecosystems also emphasize the importance of studying a range of tundra community types: extrapolations temporally or spatially have substantial risks attached.

Methane

Although carbon fluxes between tundra and the atmosphere are quantitatively dominated by CO_2, and they have received major attention from researchers, the net release of CH_4 from wetter tundra ecosystems to the atmosphere is another process that strongly couples tundra systems to atmospheric chemistry. Methane is present in the atmosphere at concentrations more than two orders of magnitude lower than CO_2, but it is increasingly of concern as a powerful greenhouse gas because, molecule for molecule, CH_4 is 21 times more radiatively forcing than CO_2. Best estimates of CH_4 flux from wet tundra range between $18-35\,\mathrm{Tg\,year^{-1}}$, but these are based upon data from restricted sample points. The potential impacts of global environmental change on net CH_4 fluxes between tundra ecosystems and the atmosphere are receiving growing attention, because atmospheric CH_4 concentrations are increasing by about 1% per year and CH_4 emissions from tundra represent almost 25% of the total global emissions from natural sources (e.g., including such sources as ruminant animals and termites). One concern is that climate warming could significantly increase rates of the anaerobic bacterial process of methanogenesis in wet tundra and mire ecosystems. This process is thought to be highly temperature-dependent and could result in significantly greater fluxes of CH_4 from tundra to the atmosphere, thus acting as a positive feedback on further environmental change. Predicting the effect of environmental change on net CH_4 fluxes is, however, highly complicated due to several interacting factors (see Figure 6). For example (i) net fluxes of CH_4 are not only temperature-dependent, but are also strongly influenced by soil hydrology and oxygen status (these factors interact because waterlogging severely restricts O_2 diffusion to depth in soils); and (ii) in aerobic soils there is also a group of bacteria called methanotrophs, which actually consume CH_4 and use it as an energy and carbon source. Thus, warming without any increase in precipitation could result in soil drying, increased O_2 availability at depth, and both increased CO_2 emissions (due to increased aerobic decomposition: as described earlier) and reduced CH_4 emissions (due both to reductions in the rate of methanogenesis and increases in the rate of methane consumption by methanotrophs, Figure 6). Assessing the overall implications for radiative forcing due to greenhouse gases is challenging, therefore, because tundra CO_2 and CH_4 fluxes can respond quite differently to the same environmental factors. Warming combined with increased precipitation is, however, likely to increase net emissions of CH_4 from tundra to the

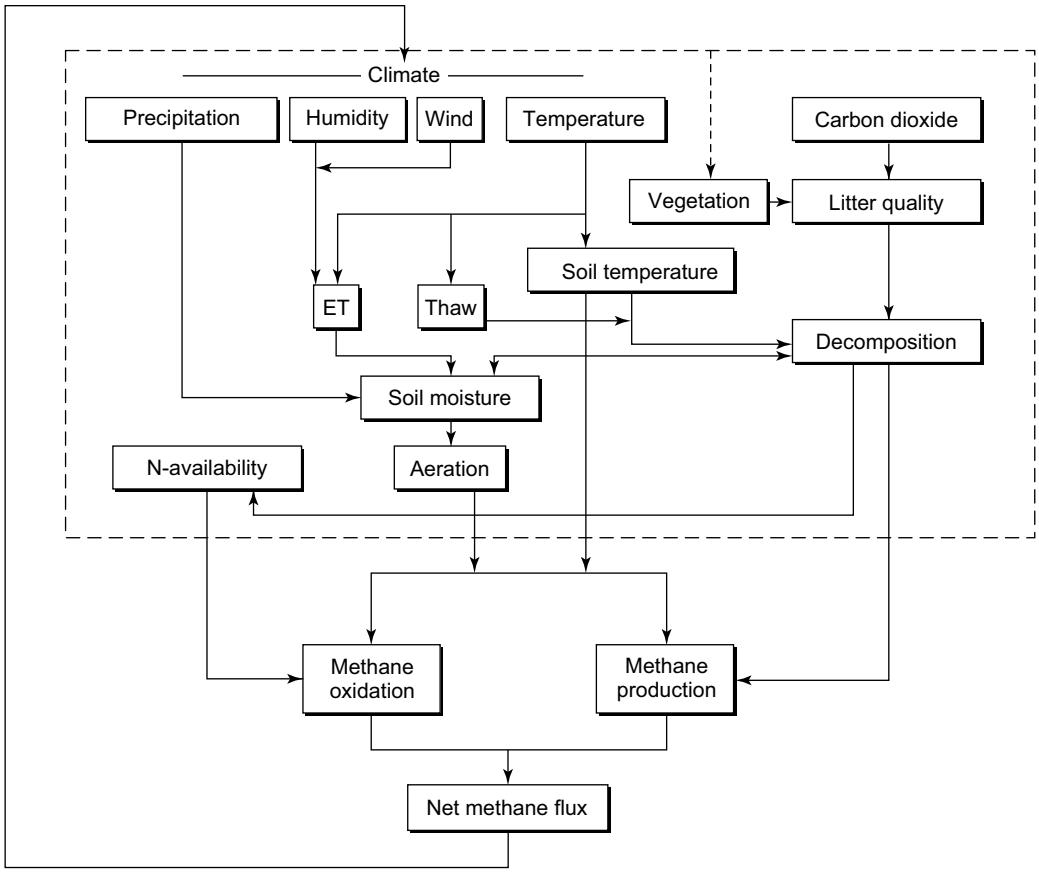

Figure 6 Some of the ecological links between climatic change and methane production and consumption in natural ecosystems. The dashed box indicates the many factors in uencing vegetation; ET, evapotranspiration. Note the suite of environmental variables that interact to in uence soil temperature and moisture regimes, and thus also aeration status. The aerobic processes of methane oxidation (methanotrophy) and the anaerobic process of methane production (methanogenesis) are strongly in uenced by soil moisture and aeration status, which in turn are in uenced by general climate. The balance between these two bacterial processes in uences net CH_4 ux, as does the effect of decomposition (supplying methanogenic bacteria with raw materials for CH_4 production, and consuming O_2 in the soil). (Reprinted from Torn and Chapin, 1993, with permission from Elsevier Science and from the authors)

atmosphere, as described in a modeling study by Christensen and Cox (1995). As yet it is impossible to predict the impacts of increasing atmospheric CO_2 concentrations and UV-B fluxes at the surface on net CH_4 fluxes, although experimental studies in, for example, temperate mire systems suggest that elevated atmospheric CO_2 concentrations could influence methanogenesis through alterations in the amount and chemistry of materials exuded from plant root systems (methanogenesis requires a supply of organic materials and decomposition products).

Nitrogen Compounds

In tundra ecosystems generally, one facet of global environmental change that has not received adequate attention is the global increase in deposition of nitrogen-containing airborne compounds: this is a striking omission, particularly since ecosystem modeling studies by Melillo *et al.* (1993) support the view that climate change impacts on NPP in northern ecosystems will be modulated via the effects of temperature on nitrogen availability (e.g., though rates of nitrogen mineralization in soils). Evidence from ice core analysis also indicates that there has been a 100% increase in nitrogen deposition at remote stations (e.g., central Greenland) since the 1950s: clearly the cumulative inputs of this biologically available nitrogen to tundra ecosystems have considerable potential to influence soil nitrogen reservoirs, NPP, net carbon fluxes and species composition (see Woodin and Marquiss, 1997 for a review).

Surface Energy Exchange and Links with the Global Radiation Budget

The energy budget of tundra ecosystems is of global environmental significance. Arctic tundra ecosystems, in particular, have a cooling influence globally, because when snow-covered, they reflect incoming solar radiation strongly

back to space. This contributes significantly to the 30% of incident solar radiation that is reflected (e.g., by snow, clouds and atmospheric particulates) without causing surface warming. Just how important tundra ecosystems are (and have been during the Holocene) to the global radiation budget and for regional climate has been demonstrated convincingly by a climate modeling study of Foley *et al.* (1994). In this study, a GCM was used to simulate the climate of the high northern latitudes (between 60–90 °N) during the mid-Holocene (about 6000 years ago), a period known to be warmer in these regions than the present. First the team ran the computer simulation as a control, with input parameters (in terms of solar energy receipts) reflecting contemporary orbital characteristics of the Earth. This provided a baseline for comparison with two experimental simulations. Exp-A was a simulation in which the orbital parameters (eccentricity – or orbital stretch – around the sun, degree of tilt of the Earth's axis, and the seasonal timing of the perihelion – the point in the orbit at which Earth is closest to the sun) were set for 6000 years ago: The changes result in an increased receipt of solar energy during the northern summer and a delay in the formation of sea ice in autumn and winter, resulting in year-round warming (relative to the control) of 1.8 °C.

Exp-B, by contrast, not only altered the orbital parameters, but also simulated an expansion of boreal forest onto what is currently tundra, in line with paleobotanical evidence for a northward extension of the tree line during the middle Holocene. This expansion of forest onto tundra produced an additional annual average warming of 1.6 °C (leading to a total of 3.4 °C warming). The explanation for this is that the modest warming resulting from changes in orbital parameters allowed the northern limit of the boreal forest to expand onto tundra: this expansion resulted in a change in vegetation canopy structure and a reduction in reflectivity (albedo), thus allowing more solar radiation to be absorbed, especially in the springtime (with lengthening days but a complete snow-cover on the adjacent tundra). The replacement of southern tundra with boreal forest thus accentuated warming caused by orbital factors. The significance of the vegetation forcing of climate, compared with the orbital forcing, is shown in Figure 7, with the springtime peak clearly evident. In the future, a significant northward expansion of boreal forest onto tundra, together with the associated changes in albedo, and possibly reinforced by reduced snow-cover in springtime on remaining open tundra, could act as a strong positive feedback on further global warming.

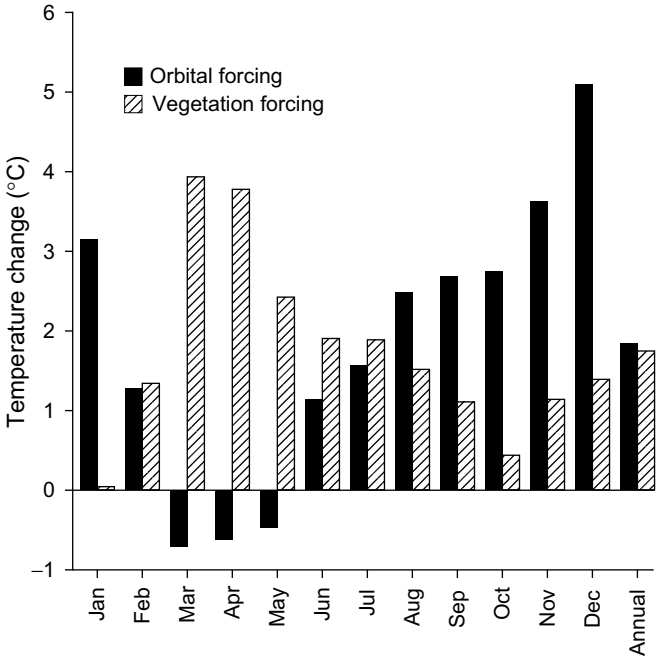

Figure 7 Changes in zonal average (over land from 60 to 90 °N) monthly surface temperatures due to orbital and vegetation forcing. The vegetation forcing component illustrates the role of boreal forest encroachment onto tundra during the mid-Holocene (6000 years before present) in reinforcing warming caused by orbital changes. The forest acts to lower albedo and re ect less solar energy to space compared with snow-covered tundra: the result is more solar energy absorbed and greater warming. Issues Relating to Biodiversity and System Stability

Tundra systems are frequently said to be *fragile*, particularly in terms of the impacts of physical disturbance. The general validity of this assertion in relation to global environmental change is, however, open to question, particularly in the light of major changes during the Quaternary and the ongoing dynamics of tundra grazing systems and physical disturbance associated with cold-region geomorphological processes (Figure 8).

Interspecific biodiversity in tundra ecosystems is low compared with many other major biomes, but within-species (intraspecific) diversity of vascular plants can be high, potentially pre-adapting plants to environmental change. For several key circumpolar arctic and alpine tundra species (e.g., *D. octopetala*, and *Saxifraga oppositifolia*), there are distinct *ecotypes* (ecotype – a locally adapted population of a widespread species – Oxford Dictionary of Botany, 1992), occupying highly contrasting micro-environments (often topographically controlled) such as snow-beds or ridge-tops. The classic study on ecotypes of *D. octopetala* by McGraw and Antonovics (1983) has demonstrated that although an ecotype growing on exposed ridge-tops (*D. octopetala octopetala*) is able to hybridize with *D. octopetala alaskensis*, occupying nearby sheltered snow-bed habitats, this may be very rare in nature due

Figure 8 A high arctic environment, Br gger Peninsula, Spitsbergen (79°N). The mantle of rock debris is actively churned by freezing and thawing processes (cryoturbation), resulting in the sorting of different sized rock material to produce patterned ground. Here primary productivity is very low and physical disturbance is of major signi cance. The ne-grained materials (darker tone, in foreground) support a cyanobacterial crust, which provides a source of inorganic nitrogen (through biological xation) and may help to stabilize the surface. If the cryoturbation is not too severe, some mosses and vascular plants (such as purple saxifrage - *Saxifraga oppositifolia*) may be able to establish themselves. The mean temperature of the warmest month is around 4.5°C

to separation in the flowering period of the ecotypes (on ridges flowering is earlier due to rapid melting of the thinner snow cover). Morphological differences in the ecotypes are maintained when they are grown under the same (common garden) conditions, demonstrating a genetic basis for the differences. In a scenario of environmental change, the presence of the two ecotypes should confer survival potential through shifts in the relative abundance of one ecotype compared with the other. Thus with greater winter/early spring snowfall, there may be stronger selection for *D. octopetala alaskensis*, the snow-bed ecotype, while a longer growing season, or thinner winter snow-cover may benefit *D. octopetala octopetala*.

Those tundra ecosystems currently characterized by incomplete vegetation cover and much bare ground (e.g., many of the High Arctic and Alpine tundras), are of interest in relation to global change scenarios and the biodiversity debate because they provide the space for new species to move in from farther south or from lower elevations (in an alpine setting). Competition may be less intense in these extreme environments, allowing immigration and, at least temporarily, an increase in species richness. This process of immigration has been noted by Grabherr *et al.* (1994) for several mountain summits higher than 3000 m in the central Alps (in western Austria and eastern Switzerland), based on contemporary census work, and historical data (from 1895–1918 and 1947–1953). Temperature records indicate a warming of 0.7°C in the region over the last 70–90 years. Although species richness has increased, for some plant species at higher elevations in mountain regions, there may be nowhere left to migrate, and increasing interspecific competition from less cold-tolerant species may pose a threat in future.

CONCLUSION

Tundra ecosystems are of major interest and importance in relation to global environmental change. These systems are strongly coupled to the global climate system via fluxes of radiatively forcing trace gases and through their influence on surface energy budgets. If current scenarios of high latitude climate change are well founded, then the aerial extent of the tundra biome is likely to decrease substantially over the coming centuries (possibly even by 32%), and Low Arctic tundra types will be forced northwards. In the High Arctic the immigration of species from farther south, and the increased colonization of bare ground, may substantially alter NPP, stocks of organic matter in biomass and soils, biodiversity and the surface energy balance. The rate of change, however, and the degree to which it could be constrained by lack of mineral nutrients, or of unsuitable surfaces for colonization and establishment, is unknown, although the limited paleoecological information from the High Arctic suggests this to be a slow process (with many systems still possibly readjusting to warming following termination of the Little Ice Age).

Invasion of Low Arctic tundra systems by tall shrubs and trees could be a much more rapid process due to infilling of tundra by expansion of boreal forests currently found in sheltered river-valleys and extending well into the tundra: such processes could be particularly rapid in the very broad forest–tundra ecotone. In organic rich soils of the Low Arctic, any temperature-induced increase in rates of nutrient mineralization could also translate within a few years or decades into increased NPP and a switch to more nutrient-demanding shrub and tree species.

Dynamic responses of tundra ecosystems to single and multiple facets of environmental change will have impacts on net fluxes of important trace gases. What is particularly difficult to judge at present is how long such readjustments take, and how persistent imbalances in, for example, net CO_2 fluxes, will last. Tundra systems have experienced rapid environmental change in the past, and they continue to be subject to marked fluctuations in physical environment (e.g., associated with flooding, ice encasement and summer snowfalls) and in numbers and distribution patterns of secondary producers (invertebrate and vertebrate herbivores) and consumers. The combination of drivers of global environmental change, can, however, be expected to result in adjustments in the structure, function and aerial extent of

tundra ecosystems globally in the future: these effects can also, arguably, manifest themselves more clearly in tundra ecosystems – in which direct human impacts (e.g., associated with land-use change) remain less intense – than in many other biomes.

Vegetation Ecosystem Model and Analysis Project (VEMAP)

William J Parton and Dennis S Ojima
Colorado State University, Fort Collins, CO, USA

VEMAP was initiated to meet the needs of the ecological community to evaluate different hypotheses of climate and carbon dioxide (CO_2) perturbations on ecological systems. The project was designed to evaluate the ecological response to changes in climate derived from current climate conditions and different levels of carbon dioxide using vegetation change and biogeochemistry models. The models used to study the vegetation response to climate changes include the mapped atmosphere-plant-soil (MAPSS), BIOME and the dynamic global phytogeography model (DOLY) (VEMAP, 1995). At the same time biogeochemical responses were evaluated using the Biome-BGC (Biome-biogeochemical cycles) model, Century, and TEM (terrestrial ecosystem model) (VEMAP, 1995). Analysis of the impact of changes in vegetation distribution on biogeochemical dynamics was also investigated.

The objective of VEMAP was to intercompare the biogeochemical response among a set of models driven by the same environmental inputs under current climate and projected climate and atmospheric carbon dioxide concentrations. Data sets representing the existing variability of climate and soils over the continental region of the US (Kittel *et al.*, 1995; VEMAP, 1995; Schimel *et al.*, 1997) were constructed as part of the project. In the first phase of VEMAP, equilibrium calculations were made for the two sets of models (biogeochemical and biogeographical models). The equilibrium calculations were derived by simulating the ecosystem and vegetation responses by running each model with monthly and daily climate files over the US, gridded into 50 km cells. Atmospheric carbon dioxide levels were represented at current levels and at a double carbon dioxide level consistent with the climate projections from various general circulation models. The climate information used for the simulations included minimum and maximum surface temperatures, precipitation, total incident solar radiation, surface humidity, and surface wind speeds. The model results indicated that the biogeography and biogeochemistry models were able to simulate similar contemporary conditions of net primary production, total system carbon, and other characteristics of the ecosystems simulated; however under the different climate scenarios and double carbon dioxide levels, the biogeochemical models displayed differential sensitivity to these altered conditions (VEMAP, 1995). The range of responses indicates that the various hypotheses of the effect of temperature, moisture, and carbon dioxide levels in uence carbon uptake, decomposition, water balance and nutrient controls in these different models.

In our recent analysis, the transient dynamics of uptake of carbon was modeled from 1895 to 1993 (Schimel *et al.*, 2001). Over this period, the uxes were highly variable as the weather varied from one year to the next, providing an indication of the sensitivity of biological processes controlling carbon uxes. The models also show that the amount of ecosystem uptake is greatly variable and thus an ecosystem can act as a source or sink depending on inter-annual and seasonal weather patterns. Land use management also emerged as an important factor contributing to transient carbon uxes from US ecosystems. In particular, the regrowth of forests on abandoned farmland (a major process in the US) and in previously harvested forests replaces carbon lost during previous decades. The VEMAP result suggests that, for the US at least, forest regeneration is between 100 and 200% as significant as carbon dioxide as fertilization (Schimel *et al.*, 2001).

This is important for the prediction of future carbon dioxide levels because while carbon dioxide fertilization will continue for the foreseeable future, regrowth of trees will slow or cease when forests reach maturity or are harvested.

Vernadsky, Vladimir

(1863- 1945)

Vladimir Vernadsky, Russian natural scientist, philosopher was founder of the Russian School of Earth Sciences which included genetic mineralogy, biogeochemistry, radiology, and biosphere study. In his book *The Biosphere* (Vernadsky, 1926), he was the first to define the biosphere from a very modern thermodynamic and biogeochemical perspective by conceiving of it as an envelope of the Earth encompassing the range from atmosphere to soils where any form of life exist naturally. In contrast to the previous definitions of biosphere by Jean-Baptiste Lamarck and Eduart Suess, which included only living organisms, Vernadsky's concept of biosphere integrated all living and non-living matters which have been affected in any way by life. Furthermore in the books *The Biosphere* (Vernadsky, 1926) and *Chemical Content of the Earth's Biosphere and its Surroundings* (Vernadsky, 1965), Vernadsky presented the holistic concept of the biosphere and the study of biogeochemical cycles of the biosphere.

Vernadsky was one of the first natural scientists to describe environmental changes caused by human activity (*History of the Natural Waters* (1933–1934) Vernadsky, 1960). In this manuscript, he emphasized the in uence of humans on the geographical distribution of aquifers (disappearance of natural rivers and lakes and formation of artificial ones) and water quality. During the most tragic time in Russian history, when many friends and colleagues of Vernadsky were put into prison by Stalin's government, Vernadsky worked on the book *Scienti c Thought as a Planetary Phenomenon* (1937–1938) (Vernadsky, 1991). In the book, he emphasized the increasing role of humans in the evolution of the biosphere and the necessity for integrated studies of the Earth as a whole (including integration of biogeochemistry with social sciences). He considered humans as part of the biosphere, and human-caused environmental changes as not an accidental, but an inevitable step in the evolution of biosphere. He suggested that human activity would result in a transformation of the biosphere into the *noosphere* – the sphere of reason. In the noosphere, human thought and activity will be the major transforming forces of the environment (*see* Noosphere, Volume 5).

Vernadsky was far ahead of his time when promoting the necessity to integrate the study of the Earth system by including living and non-living matters as well as human activities and scientific thought for future investigation of the biosphere's evolution. A unification of scientific knowledge and close scientific cooperation between different countries were among the necessary conditions proposed for the success of this integration.

Volatile Organic Compounds, Biogenic (VOCs)

Manuel Lerdau
State University of New York, Stony Brook, NY, USA

The production and consumption of volatile organic compounds (VOCs) by plants and microbes is one of the crucial ways in which ecosystems in uence the atmosphere. VOCs are organic molecules that have a low enough boiling point that they change from the liquid to the gas phase at a high rate at physiologically realistic temperatures, 10- 45 °C. Once these molecules are in the gas phase, they can diffuse rapidly from the plant or microbe to the atmosphere. Plants and microbes together produce approximately 2×10^{15} *g of VOC each year, and this quantity constitutes about 80% of the chemically reactive VOCs added each year to the atmosphere (with most of the remainder coming from fossil fuel combustion). These VOCs are primary determinants of the oxidative capacity of the atmosphere (a measure of the atmosphere's potential to remove pollutant chemicals) of the lower atmosphere, the dynamics of carbon monoxide and tropospheric ozone, and the abundance of atmospheric aerosols. Because these VOCs are produced and consumed through complex physiological processes, their rate of emission to the atmosphere is highly sensitive to changing environmental conditions such as temperature, precipitation, and land use practice. Biological exchange of VOCs thus has the potential to be a vital feedback link between global environmental change and ecosystem processes.*

INTRODUCTION

The range of VOCs produced by organisms is as large as their atmospheric impact. The most important VOCs range in size from the one-carbon methane (CH_4) through the 15-carbon sesquiterpenes ($C_{15}H_{24}$), with approximately 20 000 different chemical species found in this size range. Despite this nearly overwhelming diversity, certain patterns exist that allow one to group these VOCs by their chemical families, their impacts on the atmosphere, their biosynthetic pathways, or the taxonomic positions of the organisms that produce them. Most of the major VOCs are either alkanes such as methane (saturated hydrocarbons), alkenes (hydrocarbons with one or more carbon–carbon double bonds), or aldehydes, ketones, and organic acids (molecules with unsaturated carbon bonds and at least one oxygen).

Because they exist in low concentration in the atmosphere, most VOCs are difficult to measure. Thus our understanding of VOC emissions are often limited by development of techniques to measure them. Most VOCs are measured using gas chromatography to separate the chemical of interest from a sample of air and then a detection method such as ame ionization to quantify the compound. The identification of a particular compound is usually determined by using a gas chromatograph that is linked to a mass spectrometer. For a few of the VOCs that are particularly important in global climate and atmospheric chemistry, rapid measurement methods have been developed. For example, tunable diode lasers have been developed that allow determination of methane concentrations in nearly real time. In the case of isoprene (a compound discussed below), a chemical reaction and uorescence technique allows measurements on the time-scale of 10 Hz.

MAJOR CATEGORIES OF VOCs

Methane

Methane is the single most abundant VOC in the atmosphere, with an annual ux rate of approximately 500 terragrams (Tg, 1 Tg = 10^{12} g) of carbon per year and a standing concentration of approximately 1.8 ppm. Compared with most of the other biogenic VOCs, methane is inert in the atmosphere, reacting slowly with its principal oxidant, the hydroxyl radical (*see* OH–Radical: is the Cleansing Capacity of the Atmosphere Changing?, Volume 2). Calculations suggest that methane's atmospheric lifetime is on the order of 7–10 years. Because the entire atmosphere is mixed on the order of 1 year, methane tends to be homogeneously distributed across the surface of the earth. In the atmosphere, methane's inertness and its ability to absorb in the infrared portion of the spectrum make it one of the most important greenhouse gases (after water vapor and carbon dioxide). The oxidation of methane, although slow, is also important because it contributes to the global burden of carbon monoxide, a greenhouse gas and pollutant.

The two main sources of methane are fossil fuel related and biological. Coal mines and natural gas production both

yield methane as side products, and fossil fuel combustion produces methane as well. On a global basis, these fossil fuel sources are fairly small, combining to contribute only approximately 20% of the world's methane, with the rest derived from biological processes. All of this biogenic methane is produced through anaerobic metabolism in which a carbon source, either acetate or carbon dioxide, is reduced to methane. While acetate cleavage was almost certainly the first methanogenic pathway to evolve, both it and CO_2 reduction are found today. Many ecosystems contain anoxic zones that are sites for methanogenesis. However, those ecosystems that have oxic regions on top of their anoxic ones often have low net methane uxes because of consumption by methanotrophic bacteria living in oxic zones near the surface. These methanotrophs oxidize methane and can reduce the net ux so much that some systems, such as many forests, become net methane sinks.

The major sources of biogenic methane include rice paddies (≈20% of the total biogenic), natural wetlands (≈25%), fermentation in the guts of ruminants such as cattle (≈20%), and waste disposal sites such as landfills and sewage treatment plants (≈20%). The remaining 15% of the biogenic methane comes from a variety of small sources, including termites and freshwater systems such as rivers. These numbers indicate that approximately 60% of the global methane ux results directly from human activities and is thus potentially amenable to change if those activities are modified. For example, there is currently great interest in modifying rice cropping strategies in order to increase yields and minimize methane uxes.

Phytogenic Volatile Organic Compounds

With the exception of methane, as discussed above, all the other major biogenic VOCs are derived from plant physiological processes. The most important compounds, from the perspective of both the plant and the atmosphere, are the isoprenoids, which range in size from the 5-carbon isoprene, C_5H_8, to the 15 carbon sesquiterpenes, $C_{15}H_{24}$. Plants make many larger isoprenoids as well, but these are big enough that they have very low vapor pressures and rarely volatilize. Isoprenoids have played a large role in human affairs since long before the advent of global ecological concern. For example, monoterpenes, $C_{10}H_{16}$, have played a significant role in human history because they are major constituents of many herbs and spices, e.g., frankincense, myrrh, and rosemary. The significance of phytogenic VOCs for the atmosphere was first noted in Soviet Russia in the late 1920s, and then independently rediscovered in the United States and Soviet Georgia in the 1950s.

Isoprene

Of the isoprenoids, the most abundant, as a percentage of photosynthesis and in terms of concentration in the atmosphere, is isoprene. The annual ux of isoprene is equivalent to the ux of methane, but isoprene is much more reactive, with a lifetime ranging from minutes to tens of minutes. This high reactivity means that isoprene has an average concentration of only approximately 1–2 ppb. The high reactivity and low concentration of isoprene precludes any direct role for it in greenhouse warming. On the other hand, it is the dominant reduced compound in the troposphere and plays a major role in the chemistry of ozone and carbon monoxide.

The physiological and biochemical bases of isoprene production have only been understood in the last few years. Isoprene is produced through a complex metabolic pathway that uses two simple products of photosynthesis and respiration, glyceraldehyde phosphate and pyruvate to produce a 5-carbon sugar that is then converted to a compound that serves as the universal precursor for all isoprenoids, dimethylallyl pyrophosphate (DMAPP). When the phosphate groups are removed from DMAPP and nothing added in their stead, isoprene is formed. This step is apparently irreversible. That is, plants do not appear to metabolize isoprene, and they do not store it.

The enzyme catalyzing this final step has been well studied, and its kinetic and thermodynamic properties have been well described. The enzyme is activated by light and magnesium atoms and shows a strong pH dependency. In addition, activity of the enzyme depends strongly on temperature. Detailed studies of both isoprene uxes and enzyme activities have shown that the variability in emission from any one leaf over a time scale of seconds to minutes to hours can be explained by impacts of light and temperature on enzyme activity. What is not yet understood at all, however, is why, at the same light and temperature levels, some species of plants produce high levels of isoprene, others produce low levels, while still others appear to produce none.

There have been numerous suggestions regarding the possible functional significance of isoprene production and emission by plants. The first suggestion, made in the 1950s, was that it served as a by-product of a not-yet-identified second carboxylase in plants. This idea, however, has been completely dismissed. Next, the suggestion was made that isoprene production might serve as a sink for reductant when light harvesting exceeded the sink capacity of the Calvin cycle (the reactions of photosynthesis that consume light energy and convert CO_2 to organic forms). Energetic calculations, however, make this possibility remote. The reductant cost of isoprene synthesis is too small to confer a substantial benefit.

Two possibilities are currently considered most likely. The first is that, as isoprene diffuses from the chloroplast (its site of synthesis) to the intercellular air space, it alters the thermal stability of the membranes it passes through and makes the membranes more stable at higher

temperatures (Sharkey and Singsaas, 1995). This hypothesis is concordant with the strong positive relationship between isoprene biosynthesis and leaf temperature, but the demonstrated increase in thermal stability is very small, and there is not yet a clear biophysical mechanism for this increase in stability.

The second possibility, suggested more recently, is that isoprene production results from inefficiency in an enzyme whose primary function is in another part of the biosynthetic pathway from which isoprene is derived (Lerdau *et al.*, 1997). Studies on the kinetics of isoprene synthase fit with this theory; the enzyme has a remarkably high K_M, which suggests that its primary activity may be to catalyze a different reaction than isoprene synthesis (K_M equals the substrate concentration at which a reaction rate is one-half of its maximal value). There have not, however, yet been any direct tests of this hypothesis. For the moment, the function of isoprene production by plants remains a question open for investigation.

Terpenes

The other primary group of phytogenic VOCs are the mono- and sesquiterpenes. These C10 and C15 molecules serve diverse roles in plants, although for the most part they are involved with defense against pests and pathogens. Once terpenes are in the atmosphere, they tend to be much more involved in aerosol formation and relatively less involved in the dynamics of carbon monoxide and ozone than is isoprene. Recent evidence from studies of tropical clouds has shown that most rain water comes from transpiration and that organic compounds such as terpenes are responsible for most of the condensation nuclei, demonstrating that trees not only transpire the water that falls back down as rain, they also play a major role in cloud formation (Hoffmann *et al.*, 1998).

As with isoprene, the terpenes are made from DMAPP. In the case of the monoterpenes, two molecules of DMAPP are combined to produce the universal terpene precursor, geranyl pyrophosphate (GPP). This molecule then undergoes a series of reactions that lead to the many thousand of monoterpenes observed in plants. When sesquiterpenes are produced, the GPP combines with another DMAPP to produce a 15-carbon precursor that then becomes the final sesquiterpene product. These biosynthetic routes are well understood and have been characterized down to the molecular genetic level for some taxa.

The emission mechanism of these higher molecular weight isoprenoids is fundamentally different from that of isoprene. While isoprene is produced and immediately begins diffusing toward the atmosphere, with plants having no specialized structures or organelles for isoprene storage, the terpenes tend be stored in cavities, ducts, glands, or canals. Their emission depends on the volatility of the individual compound, its concentration in solution within the storage structure, and temperature. Together, these three parameters determine the vapor pressure of the compound and the emission is a diffusion process from the organelle to the air. Thus, unlike the case of isoprene, instantaneous emission rate is almost independent of light intensity and physiology. There have been recent reports that a few plants in the Mediterranean region of Europe emit terpenes in a light-dependent manner similar to isoprene, but it is not yet known whether these emissions are of importance outside of this region (Lerdau *et al.*, 1997). Many terpenes are emitted from tropical forest, but the relative proportions of light-independent and light-dependent emissions are not known.

Oxygenated Compounds

The third main group of phytogenic VOCs are the oxygenated compounds. Unlike the case of the isoprenoids, these compounds are classified together only by all having an oxygen molecule rather than through a common biosynthetic route. As one might expect, the oxygenated species are a highly diverse group, formed through many pathways, emitted through many different mechanisms, and serving many different ecological roles. In general, however, their atmospheric impacts are similar. The oxygenated species tend to have low vapor pressures, to be quite soluble in water, and to play important roles in aerosol formation rather than in carbon monoxide or ozone dynamics. It would be impossible to cover the full range of these compounds in one brief article, so attention will focus on a few that are notable.

One of the most abundant oxygenated VOCs is methanol. Methanol is produced when leaves are expanding as the cell walls grow, and current evidence suggests that methanol is produced as the pectin in the cell wall is de-methylated. The methyl group then becomes hydrated to form methanol. To date, every type of plant that has been examined has been found to emit methanol during leaf expansion. In contrast to methanol, with it ubiquitous distribution, another alcohol, methyl butenol, is found in only one group of pines, the yellow pines (Harley *et al.*, 1998). This compound, whose biosynthesis is incompletely understood, is the dominant VOC emitted by lodgepole and ponderosa pines, two of the most abundant trees of the western United States. It has never been found, however, as a product from any other group of plants.

Other examples of oxygenated compounds emitted by plants include acetone and hexanal, which are produced by leaves that have been cut. These compounds appear to help prevent microbial infection after injury. Also significant, although not well studied, are phytogenic organic acids, which may make up a substantial portion of the proton budget in tropical air that is not contaminated by human activities. A curious mystery of organic acid emissions is that it is not known whether these compounds are actually made by plants or whether they are produced by bacteria living on the surface of leaves.

EFFECT OF GLOBAL CHANGE ON VOLATILE ORGANIC COMPOUND EMISSIONS

There has been little direct experimental research on how global environmental change will affect the production and emission of methane and the phytogenic VOCs to the atmosphere. Certainly, however, the potential for feedback between methane emissions and greenhouse warming and phytogenic VOCs and atmospheric chemistry makes these questions paramount. The following section brie y covers four of the most significant environmental changes that are occurring on a global scale and how they might affect the emission of VOCs from ecosystems to the atmosphere: (1) warming from increased concentrations of greenhouse gases; (2) elevated CO_2 as a phenomenon that directly affects ecosystems; (3) increased deposition of nitrogen as a result of human activities; and (4) land use change as increasing amounts of land are converted to managed ecosystems.

According to most models of global change, increases in global mean temperatures are likely to occur disproportionately in high latitudes. These high latitude ecosystems are often characterized by having large amounts of accumulated organic matter, often in the form of peat. This peat, currently frozen for much or all of the year, could thaw and become available to microbes for decomposition. Much of this decomposition is likely to be anaerobic and lead to large amounts of methane production. This increase in methane could well act as a positive feedback on global temperature through methane's role as a greenhouse gas. On the other hand, if drying accompanies warming, then the proportion of an ecosystem that is anaerobic (and thus capable of supporting methanogens) may decline. Warming is also likely to affect the emission of the isoprenoid VOCs. Both isoprene and terpenes are emitted in strongly temperature-dependent manner, and the range of temperature increases suggested by most global climate models suggests that emission of these VOCs may increase exponentially in the 21st century. This change could, with the increase in reactive oxides of nitrogen that result from fertilization and fossil fuel combustion, lead to an increase in levels of carbon monoxide and tropospheric ozone, both important pollutants and greenhouse gases (Brown, 1998).

The direct effects of elevated CO_2 on methane production are harder to predict. Elevated CO_2 tends to increase the productivity of terrestrial ecosystems (*see* CO_2 Enrichment: Effects on Ecosystems, Volume 2), and this increase could lead to a rise in the deposition of organic matter to sediments and other anoxic environments. This increase in the substrate available for anaerobic decomposition may lead to an increase in methane production in many ecosystems. Similarly, as elevated CO_2 increases productivity in terrestrial systems, the standing biomass available to produce VOCs will also rise, and emissions may increase. There have been suggestions that elevated CO_2 will increase the relative availability of carbon to nitrogen in ecosystems and this will lead to a proportional increase in the production of carbon-based compounds such as isoprenoids, but experiments are only beginning to examine this possibility (Dacey *et al.*, 1994).

An environmental change that is occurring locally across the globe and may be of great relevance to biogenic VOC production is the increased deposition of reactive nitrogen (*see* Nitrogen Deposition on Forests, Volume 2). This reactive nitrogen could serve to fertilize ecosystems and lead to large increases in productivity. Increased nitrogen deposition may also increase the deposition of sediments and the production of methane. There have been several experiments showing that isoprenoid emission by plants responds strongly to nitrogen fertilization (Litvak *et al.*, 1996). Increases appear to occur both as a result of increased carbon fixation and of increased activity of the enzymes responsible for isoprenoid production. One aspect of nitrogen deposition that may alter VOC uxes is the impact of nitrogen deposition on biological diversity. It is not yet known whether nitrogen deposition will tend to favor VOC-producing species or not, but the effects could be profound.

Perhaps the single most important change in the global environment that is occurring with respect to VOCs is the extensification of agriculture, especially in tropical regions and the resulting conversion of forest to cropland, pasture, and then secondary forest. This conversion often involves the replacement of forests that contain many isoprenoid-emitting taxa with agricultural species such as corn, cassava, beans, or soy, which all happen to have very low levels of isoprenoid emission. The C4 grasses that often occur in tropical pastures also have very low levels of emissions. On the other hand, many secondary forest species, palms are a good example, have very high levels of VOC emissions. While it is difficult to make general predictions as to how VOC emissions will change in response to changes in land use, the highly species-specific nature of the isoprenoid emissions makes it likely that land use change will overwhelm the effects of other global environmental changes on biogenic VOC emissions.

Another important aspect of agricultural extensification that is likely to affect biogenic VOC uxes is the ever increasing area of land devoted to wetland rice production. As noted above, the sediments underlying rice paddies are substantial sources of methane. The large inputs of organic matter from rice production, the anaerobic nature of the sediments, and the many conduits within rice tissue that promote oxygen transport to roots combine to provide abundant substrate, an ideal production environment, and superb conditions for transport to the atmosphere of methane.

von Humboldt, Alexander

(1769- 1859)

Alexander von Humboldt (Baron) was born September 14, 1769 in Berlin, and died May 6, 1859 in Berlin. He was an outstanding research traveler, geographer and forerunner of modern ecological environmentalists such as Vernadsky (*see* Vernadsky, Vladimir, Volume 2).

After extensive study in Frankfurt/Oder, Gottingen, Hamburg and Freiberg/Saxonia (1787–1792), von Humboldt inherited property in 1796 that enabled him to pursue the life of an independent geographical explorer and researcher. On June 5, 1799 he started his famous expedition to South America (Venezuela–Cuba–Columbian Andes–Ecuador–Peru–Chile), and Mexico, returning from there via Cuba and the US (Philadelphia and Washington as a guest of President Jefferson) to Europe on August 3, 1804. Based on extensive observations, measurements, botanical collections (together with the French botanist Aime Bonpland) and physical/chemical experiments, von Humboldt started to publish the main scientific results of his extremely well prepared, meticulously planned and carefully documented research expedition to Central and South America, partly in co-authorship with Aime Bonpland, in 36 volumes entitled *Voyage aux régions équinoxiales du nouveau continent fait en 1799, 1800, 1801, 1802, 1803 et 1804, par Alexander de Humboldt et A Bonpland*. This monumental collection and documentation contains regional descriptions and botanical, geographical, geological, astronomical and zoological observations and analyses, most of it written during his stay in Paris (1807–1827) and published in French between 1805 and 1834. Besides this *chef d'oeuvre*, parts of von Humboldt's work were published separately and have been well received. These books include *Ideen zu einer Geographie der P anzen nebst einem Naturgemälde der Tropenländer* (1807), which basically is an atlas of vegetation, and *Ansichten der Natur* (1808), in which, for the first time, von Humboldt's ideas of a comprehensive and holistic interpretation of natural environments and the close interactions of geosphere, biosphere and atmosphere became apparent. The five volume (and atlas) *Essai politique sur le royaume de la Nouvelle Espagne* published between 1808 and 1811, and his *Essai politique sur l ˆle de Cuba* (1826) are predecessors of regional geographies, with a strong emphasis on the interactions between nature and society while being, at the same time, highly political in their anti-slavery discourses.

Among his later expeditions and explorations, the Russian–Siberian expedition (April 12 – December 28, 1829) is especially worth mentioning, because it was planned as a comparative and complementary endeavour to his great American expedition. However, the resulting publication *Asie Centrale. Recherches sur les chaines de montagnes et la climatologie comparée* (Paris, three volumes, 1843) indicates that the aims and scope of this trip were much more limited.

von Humboldt's great and lasting achievements in regard to a holistic-integrative world view are based on innovative scientific methodologies, with the ultimate goal of discovering connections and interrelationships between the physical and biological spheres at the Earth's surface. The use of sophisticated new instruments, accurate observations and quantitative measurements provided analyses of ora and fauna, topographies and climatic data. Thus, von Humboldt's expeditions solved a great number of geographical riddles (e.g., the connection between the Orinoco and the Amazon catchment areas via the Casiquiare), and introduced new conceptual tools for presentation of his findings. Using isolines for the first time, von Humboldt produced the first map of global isotherms, as well as three-dimensional vegetation patterns in the tropical Andes, revealing their interrelationship with climate and weather, topography and

geology as well as with culture. These are probably his most outstanding and lasting achievements in this regard.

The very essence of von Humboldt's new way of looking at our planet is laid down in his monumental, partly posthumous *Kosmos. Entwurf einer physischen Weltbeschreibung* (five volumes and one atlas; 1845–1862). In particular, volume one of *Kosmos* contains the foundations of von Humboldt's holistic–ecological view of our natural environment and its analysis well in advance of his geographical contemporaries: In der Lehre vom Kosmos wird das Einzelne nur in seinem Verhaltnis zum Ganzen, als Theil der Welterscheinungen betrachtet (volume one, 1845, p 40). The plea to describe, analyse and understand each single part of our natural environment, in relation to the whole and as part of the total cosmos was von Humboldt's main goal. Being well aware of the methodological problems of such an attempt, von Humboldt used the metaphor of producing ein allgemeines Naturgemalde als Ubersicht der Erscheinungen im Kosmos (p XII), a general tableau of nature as a holistic entity of all expressions of the cosmos. Nature, as such, became a scientifically relevant object of analysis, with natural landscapes (*Naturlandschaften*) being their visual and objectively experienceable expression. However, the totalcharakter of a landscape is only the exterior expression of an innere Verkettung des Allgemeinen mit dem Besonderen (ibid.), i.e., the inner combination/interaction of the general with the specific. Thus, the integration of different kinds of phenomena, each, however, in its specific setting, are the basis for von Humboldt's attempt to understand the cosmos and its various regional and ecological differentiations. *Cosmography/Weltbeschreibung* – a term adapted from the philosopher Kant – thus became the study of all that has been created, of all aspects of nature that exist in a geographic context on Earth (things and forces of reality) as well as their simultaneously existing natural totality (*Naturganzes*!). With such an approach, von Humboldt became not only one of the most in uential scientists in the Age of Enlightenment, but also one of the most important forerunners of a new and extremely modern concept for the Earth sciences and of a holistic–integrative approach towards analysis and understanding of the interrelationships of diverse orders in nature.

Weed

A *weed* is any plant that interferes with some human purpose. The fact that many pretty garden plants (e.g., purple loosestrife, *Lythrum salicaria*), once introduced to new locations around the world, became aggressive weeds emphasizes the subjectivity and context dependence of the term weed. In the context of agriculture and forestry, weeds interfere with the growth of crop plants and a variety of control methods are available. The choice of method depends on its environmental impact, the characteristics of the weed species, and the resources (e.g., personnel, time, budget, equipment) available.

Ecologically, weeds are usually r-strategists and dangerous as biological invaders. They often proliferate shortly after a disturbance (e.g., plowing, harvesting) because of their efficient exploitation of the relatively free access to abundant resources then. There are four principal mechanisms by which weeds establish their large, post-disturbance populations: (1) individuals of some weed species (e.g., bunchberry *Cornus canadensis*) survive the disturbance and grow vigorously under the strong light penetration of the disturbed crop canopy. These weeds may flower abundantly and set many seeds, and temporarily dominate the site. When the canopy closes and competition from neighbouring plants increases again, these weed populations decline. (2) Some weeds (e.g., pin cherry, *Prunus pensylvanica*) persist as large populations of viable seeds, living in a diapause state until disturbance stimulates them to germinate, often by exposing the seeds to sunlight. Many of these seeds grow to maturity in the resource rich conditions and reproduce profusely, leaving another generation of persistent seeds buried in the soil to await the next disturbance. (3) Other weed species (e.g., birches, *Betula papyrifera*, in a forestry context) may survive the disturbance in small numbers, but then seed abundantly and establish a cohort of new individuals. (4) Lastly, and perhaps most commonly, many species (e.g., goldenrods, *Solidago* spp., and fireweed, *Epilobium angustifolium*) invade the disturbed site, usually through wind-dispersed, or sometimes through animal-dispersed seeds.

Once established, weeds compete with crop plants for light, water, and nutrients. On rangelands and pastures, weeds may be unpalatable or even harmful to animals and reduce the quality of animal products. For instance, foxtails (*Alopecurus* spp.) can become stuck in horses' mouths; the price of wool drops when cockleburs (*Xanthium* spp.) are lodged in it.

Many weeds host insect pests or plant disease organisms. For instance, prickly lettuce (*Lactuca scariola*) provides a reservoir for downy mildew.

RICHARD A FLEMING *Canada*

Whittaker, Robert H

(1920–1980)

Robert H Whittaker, was one of the giants of ecology, who by blending penetrating theoretical insights with landmark empirical studies helped rewrite the dominant theories of how ecological communities are organized. A brilliant and honored researcher, he was an equally dedicated mentor. Among my colleagues at Cornell University, none placed

more importance on training the next cadre of ecologists than did Bob Whittaker; hence, it is not surprising that the students he trained are among the leaders of their generation. His undergraduate text, *Communities and Ecosystems*, remains a gem a quarter of a century after he wrote it, still timely despite the advances in ecology in the intervening years.

Whittaker's great contributions began with his 1948 doctoral thesis (at Illinois), in which he examined the patterns of plant species distributions along altitudinal gradients in the Great Smoky Mountains. This in itself was rather remarkable, since he was a student in the Zoology Department, rather than the Botany Department, which had denied his candidacy because of his insufficient background in botany. Whittaker was a student of Charles Kendeigh, after his original adviser Victor Shelford retired. But it was perhaps Arthur Vestal who had the greatest influence upon him, by stimulating him to question the prevailing dogma, advocated by F E Clements, that plant communities were like super-organisms, collections of species that had coincident distributions and coevolved as units. Whittaker carefully mapped out the distributions of plant species in the Smokies, and showed that this was not the case at all; rather, species were distributed individualistically, as H A Gleason had argued. Whittaker thus demonstrated that communities were fuzzy, albeit useful, concepts, whose borders were arbitrary and membership ephemeral; they could not, hence, represent evolutionary units because they did not maintain sufficient integrity and continuity over time. This finding, which surprised Whittaker, remains influential today, and undergirds the recognition that the homeostatic properties of ecosystems and the biosphere must be recognized as emerging from selection acting on their member species rather than on the system as a whole.

Though his demonstration that species were distributed continuously in space was Robert Whittaker's most enduring contribution, the scope and magnitude of his other work was daunting. He continued his analysis of vegetation with work in the Siskiyous and on the Saguaro cactus of the Santa Catalina Mountains (with W A Niering), winning the Mercer Award of the Ecological Society of America for the latter work. His empirical work led him to pioneer (with H G Gauch, Jr) the application of multivariate ordination methods to species distributions, revolutionizing and dominating the subject. With G M Woodwell he wrote a long series of seminal papers on the effects of gamma irradiation on plant communities, and on patterns of primary production. With G E Likens and F H Bormann he published fundamental work on the Hubbard Brook ecosystem, and with Likens extended this to assemble influential summaries of world distributional patterns of production and biomass. With P P Feeny and T E Eisner he explored the chemical dimensions of ecology; and with S A Levin and R B Root, the interface between population biology and community theory. Indeed, perhaps the most remarkable aspect of Whittaker's career was not his studies of diversity, but the diversity of his studies. His work touched on every dimension of ecology; from physiology to ecosystems, from populations to communities. Few before him or since have shown such breadth of scope and depth of insight.

Wilson, Edward Osborne

(1929–)

Edward Osborne Wilson, US biologist, writer, and philosopher, a native of Alabama and graduate of that State's university (BS, 1949; MS, 1950) and of Harvard University (PhD, 1955), has earned great distinction in several fields of scholarship. An international leader in the study of biodiversity and an effective spokesman for its conservation, Wilson has distinguished himself through his seminal contributions to evolutionary biology and biogeography, including the co-development (with R H MacArthur, 1967) of the theory of island biogeography. Wilson's lifelong focus on the study of ants has not only been of central importance for our modern understanding of the evolutionary relationships and systematics of that important group of insects, but led him to carry out important investigations and develop fruitful hypotheses about the nature and evolution of social behavior in insects generally. He has been involved in these studies especially concerned with the role of *pheromones*, active hormones outside of the bodies of the animals that produce them, in determining the behavior of social insects. Wilson's innovative development of the theory of sociobiology and his courageous championing of this important field of investigation has led to a great deal of important scholarship concerning the role of genetics in the determination of behavioral characteristics in

human beings and other animals. These considerations are of central importance in understanding the role of mankind in nature, and thus in the determination of our common future. Wilson's often moving and uniformly eloquently-written books including *On Human Nature* (1978) Pulitzer Prize, 1979; *Biophilia* (1984); *The Ants*, with Bert Holldobler (1990) Pulitzer Prize, 1991; and *Consilience* (1998) have been widely influential.

In the last title, Wilson argues for the unity of all human knowledge and the primacy of a small number of what he considers to be fundamental natural laws that underlie every branch of learning. No one has contributed more to the development of our common awareness of a shared dependency on the living world, or of our appreciation of the disastrous consequences of the rapid changes it is undergoing now.

Woodwell, George Masters

(1928–)

G M Woodwell is a native of Cambridge, MA, a graduate of the Boston Public Latin School, holds degrees from Dartmouth College (AB, 1950) and Duke University (AM, 1956; PhD, 1958), and is the recipient of various honorary degrees. He held a commission in the US Navy between 1950 and 1953 and has held appointments and lectureships at various universities. Between 1957 and 1961 he was Assistant and Associate Professor of Botany at the University of Maine in Orono. He joined the staff of the Biology Department of Brookhaven National Laboratory in 1961 and remained there until 1975, when he founded and became the Director of the Ecosystems Center at the Marine Biological Laboratory (MBL) in Woods Hole. He held various positions including Deputy Director of the MBL, Assistant Director for Education, and Distinguished Scientist. In April 1985 he founded the Woods Hole Research Center, an institute for global environmental research of which he is Director and President. He held an adjunct appointment as Lecturer in Ecology at Yale University for many years.

Dr Woodwell's research has been on the structure and function of natural communities and their role as segments of the biosphere. He has worked extensively in forests and estuaries in North America and has made well-known studies of the ecological effects of ionizing radiation and the circulation and effects of pesticides and other toxins. He has, for many years, studied the biotic interactions associated with the warming of the earth.

Dr Woodwell has published more than 300 papers in ecology and has contributed articles to *Science*, *Scientific American*, *BioScience*, *Ecology* and the *Journal of Ecology*, among others. He has edited books on the effects of nuclear war, the global carbon cycle, biotic impoverishment, and satellite imagery used in measuring the area of forests globally.

Dr Woodwell is a member of the National Academy of Sciences and a Fellow of the American Academy of Arts and Sciences. He was the recipient of the 1996 Heinz Environment Prize.

Dr Woodwell was President of the Ecological Society of America in 1977–1978. He was a founding trustee and is Vice-Chair of the Board of the Natural Resources Defense Council; was a founder and remains an honorary member of the Board of Trustees of the Environmental Defense Fund; was a founding trustee of the World Resources Institute, and was a board member (1970–1984) and Chair (1980–1984) of the Board of Directors and is currently a member of the National Council of the World Wildlife Fund. He was Chair of the 1982 Conference on the Long-term Worldwide Biological Consequences of Nuclear War. He is former Chair of the Ruth Mott Fund of Flint, Michigan, a former member of the Board of Trustees of the Center for Marine Conservation, and currently serves on the advisory board of the Duke University Nicholas School of the Environment.

Preface to the Encyclopedia of Global Environmental Change

THE ENVIRONMENT

The word *environment*, whose dictionary meaning is simply that which surrounds, has in the last few decades become a buzzword , encompassing an exceedingly diverse array of elements and social issues. Taking the original meaning as a point of departure, it is clear that we humans depend totally on the environment provided by planet Earth for the food we eat, the water we drink, and the air we breathe. Thus changes in this environment must be of vital concern. Will Earth continue to sustain humans in a way that also encourages the ourishing of the other living things with whom we share the planet? This question has loomed ever larger as it has become more evident that human activities have been inducing major changes in all of the compartments of the global environment. We have converted forests and savannas to farms and cities; we have exhumed ancient treasures of fuels and minerals; we have used the rivers and winds as convenient sewers; and we have released entirely new chemical compounds and organisms into the environment. In the 1960s, the scienti c community began to use the word *environment* in this new non-specialist sense. Soon too, Departments of the Environment were created by many governments, and new scienti c journals began publication while others were re-named. For example, the *International Journal of Air Pollution* became *Atmospheric Environment*! In the ensuing decades, the world community has come to see the environment in many different ways, as a life-support system, as a fragile sphere hanging in space, as a problem, a threat and a home.

GLOBAL ENVIRONMENTAL CHANGE

A broader and deeper understanding of the global aspects of environmental concerns emerged in the 1970s and 1980s, and a new phrase *global environmental change* acquired popular currency. Paleoresearch had revealed that environmental change was far from new, and by no means the sole result of the actions of heedless humans. Since the planet s formation, virtually every element of its environment has been undergoing massive changes on all space and time scales. Oxygen waxed and carbon dioxide waned in the atmosphere. Continents moved about the planet s surface like scum on a soup kettle. Great ice sheets grew and shrank. Above all, the force of life (the biosphere) emerged as a dominant driver of planetary change.

However, another vital insight began to emerge about 1980: the inescapably interlinked nature of these many environmental changes. On the very longest time scales, continental drift moved lands into different climates but also changed the climate of the globe itself. Photosynthetic life changed the atmosphere but also made possible more advanced life forms that could take advantage of the new environment. On shorter time scales, atmosphere and ocean often interact to produce the massive changes in the Southern Paci c that we term El Niño and La Niña, whose consequences extend across the planet, and profoundly affect even our socioeconomic systems. Indeed, we have come to realize that human-induced perturbations in the environment are becoming increasingly large, and are potentially coming to dominate the natural workings of the complex and interdependent global system that sustains life on Earth. Humans and their global environment are no longer independent; they are ever-increasingly becoming interdependent components of a single global system.

Thus, the term *global environmental change* has come to encompass a full range of globally signi cant issues relating to both natural and human-induced changes in Earth s environment, as well as their socioeconomic drivers. This implicitly includes concerns for the capacity of the Earth to sustain life that have motivated the development of studies of global change and sustainable development in the last few decades. Analyses of global environmental change therefore demand input from the social sciences as well as the natural sciences (and indeed also from the engineering and health sciences) necessitating an inescapably interdisciplinary approach.

Scientists from many disciplines have been attracted to this growing eld of global environmental change. This is particularly noticeable in the biological sciences through the encouragement of IGBP (International Geosphere Biosphere Programme), which invites ecologists to expand their eld of vision from the plot and landscape scales to the regional, continental and global ones, and to interact with scientists from other disciplines in exploring environmental change at these larger scales. Indeed this trend has encouraged publishers and scienti c societies to introduce new journal titles, and these publications from all accounts appear to be ourishing.

At the same time, human social, economic, and cultural systems are rapidly changing under the in uence of growing globalization. In the economic sphere, for example, today s discourse centers on multinational corporations, the Global

Economy, and the Globalization of Trade. Thus, the agendas of most of the physical, life, and social sciences increasingly focus on global-scale changes.

THE EVER-CHANGING ENVIRONMENT

Since the launching of Earth-viewing satellites, we have been able to see a constantly updated moving picture of our planet. Great weather systems sweep around the globe, waves of green and brown ebb and flow over the continents with the seasons, as do white waves of ice and snow. Nevertheless, a remarkable feature of the Earth system has been its relative stability. Since the dawn of life, the planet s environment has remained within a range of conditions that has supported life. Moreover, with some notable and perhaps cautionary exceptions, changes from year to year, decade to decade, millennium to millennium, have been modest, particularly during the last 10 000 years. Many features of human society exhibit similar behavior. Civilizations and cultures evolve slowly for the most part in response to environmental, economic, and social driving forces over their long lives. Great cities like Rome endure through the ages. A citizen of ancient Babylon probably would have little difficulty understanding the politics of modern Toronto.

But today we appear to be entering an era of change unprecedented since Babylon was a cluster of mud huts. There are many reasons to believe that changes greater than humankind has experienced in its history are in progress and are likely to accelerate.

Virtually every measure of human society numbers of people and automobiles, airplanes, energy consumption, generation of waste is increasing exponentially. While the values of a few indicators are leveling off, the magnitudes of annual increases of others remain immense.

Major changes are becoming evident in many critical elements of the environment increasing carbon dioxide concentrations, stratospheric ozone depletion (not to mention the stratospheric Antarctic ozone hole and the possibility of a similar Arctic event), rising sea level, declining productivity of soils, widespread collapses of fisheries, dramatic declines in biodiversity, destruction of tropical forests, etc. Within living memory, the countryside around large cities has been swallowed up by suburban developments and highways. Humans are stepping on the gas pedal of the planet s environment, and perhaps recklessly breaking the survivable speed limit of global change.

Paleoclimatological studies have shown that the stable environment that we take for granted has not always prevailed. Indeed, the relatively brief period in which human civilization has developed is somewhat unusual in its equable stability. Neolithic hunters in Europe some 13 000 years ago saw their climate shift from temperate to glacial in a single short lifetime. The evolution of human society is punctuated by wars, pestilence, and technological revolutions. Major perhaps even catastrophic change could occur in the future, because we know it has occurred in the past.

Rapidly advancing understanding of both natural and human systems and above all the ability to translate that understanding into quantitative models has enabled us to explore the future of our global society and its global climate with unprecedented realism. Although prediction of the single future path that we will follow is inherently unpredictable, it is possible to map a broad range of future environmental trajectories that we might take, each completely consistent with our understanding of how the system works. Such scenario-building exercises amply confirm our concerns that the changes of the 21st Century could be far greater than experienced in the last several millennia. Business-as-usual for human society appears to imply business-as-highly-unusual for the global environment.

THE INTERLOCKING BIOGEOPHYSICAL – SOCIOECONOMIC SYSTEMS

Recognition came in the 1970s that many of the environmental issues are inter-connected through the biogeochemical cycling of trace substances, especially carbon, sulfur, nitrogen and phosphorus. In fact, in a prescient statement on the main environmental research priority of the 1980s, Mostafa Tolba (then Executive Director of the United Nations Environment Programme) and Gilbert White (then President of the Scientific Committee on Problems of the Environment) drew the attention of both the scientific and the science-policy communities to the need to understand the major global biogeochemical cycles in order to maintain the global life support systems in a healthy state (Tolba and White, 1979). Quoting from that statement,

> We draw attention to the fundamental scientific importance of understanding the biogeochemical cycles which link and unify the major chemical and biological processes of the Earth s surface and atmosphere. The results will have practical significance for all of us who inhabit an Earth with limited resources and who, by our actions, increasingly affect the quality of the human environment.

So it is that many of the global environmental issues acid rain, stratospheric ozone depletion, climate change, nitrogen over-fertilization are inter-related through the global biogeochemical cycles.

One of the interesting results of the study of the Earth s history has been the discovery of the global teleconnections of the Earth system, with some major climatic shifts occurring simultaneously in the two hemispheres. In an analogous way, there has been recognition for a long time that human social, economic, and cultural systems are globally inter-related. That these are connected in turn to the

Earth system was implicitly recognized as early as the 1972 Stockholm Conference on the Human Environment.

To manage the human responses to this enormously varied but at least moderately coupled world system in an era of increasing global change through the diverse array of local, national and international organizations is indeed a daunting challenge. An essential first step is to describe past and present states, then to explain the various phenomena observed, and finally to develop predictive models (or at least a range of scenarios) describing the future behavior of this total Socioeconomic Cultural Environmental system. In this process, environmental scientists must learn how to assimilate better the new information constantly being received, although uncertainties, often large, will continue to exist. Within this mix, rational and effective policies must be developed that will balance the risks and costs of global environmental change in an adaptive way. Only then will we be able to even formulate, much less start to implement, rational and effective policies that cope effectively with global change. The prospect of change tempts us to think in terms of winners and losers. However, such analyses often do not play out in simple ways. For example, a modest increase in rainfall would cause farmers to rejoice while vacationers would despair. However, greater farm production can lead to lower commodity prices, thereby reducing farm incomes while making vacation food purchases less expensive. Human society is pretty well adapted to the present environment, so change is necessarily a challenge.

In the longer-term, much depends on the ability of societies to respond, to adapt. Societies will differ in the resources natural, human, and technological that are available to them. They will also differ in terms of the values and priorities they attach to physical, social, and environmental goals, and in the social and political mechanisms that they employ to seek these goals. These differences in the human world of generations yet unborn may be as great and as significant as the changes in the global environment. A major challenge for our times is to develop frameworks for understanding complex interdisciplinary issues of this complexity.

No discussion of change and the future can be complete without consideration of risk. Projections of the future, however imaginative or soundly based, necessarily center on plausible, surprise-free scenarios population will increase, economies will advance, climate will change all typically slowly and smoothly. However, such projections made at the beginning of the 20th Century would have missed two World Wars, the automobile, aviation, space travel, television, and McDonald s in Beijing. By definition, genuine surprises cannot be predicted. However, an understanding of the impacts of past surprises may help us to make our society and our world somewhat more robust in the face of the unknown surprises that await us.

THE HUMAN DIMENSIONS OF GLOBAL ENVIRONMENTAL CHANGE

The human dimension of global change has been defined as the ways in which individuals and societies contribute to global environmental change, are influenced by it, and adapt to it. Many empirical studies have been undertaken that describe human activities in physical terms, based on various kinds of indicators. Rates of deforestation, urbanization, and changing levels of emissions of greenhouse gases are only some measurable contributors to environmental change. But the dynamics of human activities and global change are much more complex, and they reflect the complexities of the human nature relationship.

While the sheer burden of human activity on the planet is important, we know that the major forces at work are human beings operating together through political systems, corporations, interest groups, and beliefs that sway whole peoples. These raise questions about the nature of choice, about the hopes, dreams, and frustrations that impel people forward, or block them. At the moment, for instance, the dream of the good life which has been a critical element of every religious tradition in the world is increasingly being defined in terms of material possessions and powerful images that are shown on global media. Can this particular version of human happiness be sustained on a limited planet? Some people say that it can; others say that it cannot.

The central questions about the role of human beings in global environmental change revolve around social, cultural, economic, ethical, and even religious issues. These are becoming more and more pressing, and more and more foundational as human beings deliberately or inadvertently modify more and more of the planet. It is also obvious that in this generation the modification of organisms and ecosystems may well extend to the modification of human beings themselves. Among the fundamental questions are: What motivates us towards saving or harming the environment? How do we see ourselves with regard to nature? What is our responsibility to this and future generations? Who do we think we are, and who would we like to become? Appropriately enough, Volume Five of this Encyclopedia wrestles, in many different voices, with these ultimate questions that remain intimately linked with the sweep of physical, chemical, biological, geographical, and institutional changes documented and discussed throughout the earlier four volumes.

The Brundtland philosophy urges us not to reduce options for future generations. Implementation of this idea is, however, difficult. For example, it often seems more compelling to alleviate current poverty than to protect the environment and renewable resources for future generations. Many scientists agree that new approaches are needed to meld the social with the natural sciences in the policy arena. Some of the new methodologies that go beyond the physical sciences

are described in Volumes Four and Five of this Encyclopedia, e.g., post-normal science, integrated environmental assessment, and the precautionary principle.

In a commentary in which he described the 21st Century as the century of the environment, Edward O. Wilson began by referring to the growing *consilience* (the interlocking of causal explanations across disciplines) so that the interfaces between disciplines become as important as the disciplines themselves. He then stated that this interlocking amongst the natural sciences will in the 21st Century also touch the borders of the social sciences and humanities. In the environmental context, environmental scientists in diverse specialities, including human ecology, are more precisely defining the arena in which that species arose, and those parts that must be sustained for human survival (Wilson, 1998).

This is a major challenge for environmental scientists. Already through DNA techniques, for example, it is possible to trace back connections amongst prehistoric peoples through the last Ice Age to modern times.

THIS *ENCYCLOPEDIA OF GLOBAL ENVIRONMENTAL CHANGE*

More than two million papers are published every year in science and medicine, a twentyfold increase since 1940 that taxes the resources of concerned citizens, scientists, university departments, research institutes and libraries. At the same time, many policy-motivated organizations find it difficult to draw together the necessary expertise for resolving the newly emerging environmental issues. The scientific literature relating to the environment is burgeoning. However, research syntheses are in general still scattered across a broad spectrum of journals and books, and information on global environmental change is not readily available in an inter-related way. In particular, it is quite uncommon for contributions from the natural sciences to appear in the same journal or workshop proceedings as contributions from the social sciences and the humanities.

This *Encyclopedia of Global Environmental Change* is a comprehensive and integrated reference in the broad area of global environmental change that will be conveniently accessible and productively usable by students, managers, administrators, legislators, and concerned citizens. The Encyclopedia consists of five volumes of interrelated material:

Volume 1 The Earth system: physical and chemical dimensions of global environmental change (Michael C MacCracken and John S Perry, editors)

Volume 2 The Earth system: biological and ecological dimensions of global environmental change (Harold A Mooney and Josep G Canadell, editors)

Volume 3 Causes and consequences of global environmental change (Ian Douglas, editor)

Volume 4 Responding to global environmental change (Mostafa K Tolba, editor)

Volume 5 Social and economic dimensions of global environmental change (Peter Timmerman, editor)

The first four volumes cover the broad issues of the science and politics of global environmental change. Volume Five adds an often understated but extremely important aspect, linking as it does, global environmental change to the socioeconomic, cultural and ethical dimensions of human societies. Here will be found a rich panoply of writings by people who are not natural scientists but who have thought deeply about the environment. It places global environmental change in a refreshing historical, sociological and cultural context. In many contributions, the time horizons of most interest are the last hundred and the next hundred years. However, some contributions dip backward millions of years. Throughout, the emphasis is upon the dynamics of the various processes discussed how and why did they change? A second recurrent theme is the interconnection of processes and changes What produces change? What is impacted by change? Finally, we attempt to deal even-handedly with natural and human-induced change, and with impacts on both the natural world and human society. From the numerous diverse articles in the Encyclopedia, we believe that the user can obtain a coherent picture of this complex and dynamic system of which we all are a part.

To assist in promoting this coherence, each volume begins with a group of extended essays on major topics that embrace the field covered in that volume. These are intended to provide an introduction to the topic, a convenient road map through cross-references for exploring the Encyclopedia. Then there follows, in alphabetical order, shorter articles on a variety of scientific topics, descriptions of scientific programs, definitions, acronyms, and biographies of leading contributors to the field from Charles Darwin, through the Russian ecologist Vernadski, to the three most recent environmental Nobel Laureates Crutzen, Rowland and Molina. Indeed, these definitions, biographies and acronym definitions are, we believe, a uniquely valuable feature of the Encyclopedia. In the case of acronyms of international organizations and programs, it is no exaggeration to state that a young environmental scientist requires not only a good understanding of science, but also a good knowledge of acronyms, if they are to follow the discussions taking place at many international meetings! Also included in the alphabetic listings are abundant cross-references to related topics in the same or other volumes.

The substantive scientific articles that comprise the meat of the Encyclopedia are original contributions by active scientists from around the world, and thus

represent authoritative and up-to-date summaries of the state of current knowledge, direct from the producers of this knowledge. A number of these articles break new ground in synthesizing and summarizing our understanding from novel viewpoints and in unconventional ways. Thus, readers will find a wide variety of styles and approaches within the articles, reflecting in a unique way the rich diversity of today s world science. The articles have also had the benefit of careful reviews, particularly by our Editors.

The scientific essays and some of the program descriptions begin with a few italicized paragraphs written for non-specialists. These are not intended to be abstracts of the paper to follow, but rather are aimed at providing the reader with an introduction into why the topic is important and where it fits into the broader aspects of global change a kind of encouragement to read on. Reading on should not be too difficult a task, since most of the scientific essays are written at the level of journals such as *Scienti c American* and *AMBIO* that are intended for the non-specialist. The Encyclopedia will be a valuable source of information for everyone with a general interest or a need-to-know in the various environmental fields (the natural sciences, socio-economics, engineering, the health sciences, and policy analyses) particularly as they relate to global-scale environmental change, its drivers, and its consequences. It is also expected that among the audiences for each volume will be practitioners and researchers in the fields covered by the other four volumes. We believe that this rather unusual indeed unique Encyclopedia will be used in a variety of ways.

1. Some people will employ it simply as a convenient source of information on specific topics What has been happening recently to the sea ice in the Arctic Ocean? Who was Roger Revelle? What is soil mineralization? What is ICSU or IGBP? What is the Kyoto Protocol? What is deep ecology?
2. Serious students in the environmental sciences may begin by reading one or all of the introductory essays, which present highly compressed crash courses in a range of central topics.
3. We believe that the substantive specialized articles that constitute the bodies of the volumes are productively and enjoyably readable in their own right.
4. Finally, a case has been made by one of the volume editors (Peter Timmerman) for encyclopedia browsing as an enjoyable and productive pastime (*see* Encyclopedias: Compendia of Global Knowledge, Volume 5).

We believe that these five volumes are in the tradition of the human aspiration towards the compilation of global knowledge that sparked the preparation of the first encyclopedias in the 18th Century.

Our Editors have had the benefit of a marvellous postgraduate education in the course of the Encyclopedia s evolution! We are immensely grateful to the many, many authors in our virtual university who have contributed their wisdom to this project.

ACKNOWLEDGMENT

Many helpful comments and draft paragraphs were received from the Volume Editors during the preparation of this Preface.

Preface to Volume Three

The character of the Earth s surface is constantly changing as a result of the interactions of the great circulations of energy, water and materials that create the biogeochemical cycles between the atmosphere, hydrosphere, lithosphere, cryosphere and biosphere. These cycles are the sum of the processes that make ecosystems what they are at particular places and times. The processes involved will continue whatever astronomical, geophysical, biological and people-driven events do to the Earth, but their nature is constantly being modified. People meet their needs by altering biogeochemical cycles. They divert substances along new pathways, transforming them to create new goods and services. In doing so they also generate by-products, gaseous and liquid emissions and solid matter, all of which add to modifications of the biogeochemical cycles and thus to global environmental change.

These human actions have to be seen as part of a whole Earth system that is changing and producing feedbacks and responses. Some of these impacts are readily expected, but others are less easily anticipated. Some take place where the changes have occurred, such as subsidence above mine workings, but others occur far away. One example of the latter is the effect of acid rain created by industrial emissions in an industrial region on lakes and rivers hundreds of kilometers away. These connections also have a time aspect. For example, most engineering works, including large structures, dams, pipelines, flood and coastal defences, are usually designed to last 100 years or more, assuming that on average the environment will not change. When the structures are designed, historical records are used to estimate the magnitudes of major floods and storms. It is assumed that the frequency of occurrence of events of a given magnitude will not change for at least 100 years after the structure is built. Global environmental change now tends to make such assumptions invalid. Major weather systems, cyclone tracks and events like El Nino and La Nina are becoming less predictable. Already local environmental changes are affecting floods, as many people living on floodplains have already found. Floods of a given depth have become more frequent because land use changes have altered rates of runoff, especially in small highly urbanized watersheds.

To unravel these interactions, feedbacks and causes, holistic thinking is required. Ecology helps in developing this, by looking at organisms in their habitat and their interactions with other organisms and their environment. The extension of ecology from the study of plants and animals in specific habitats to the study of interactions amongst people, other organisms and their environment requires the inclusion of social processes. The resulting analysis of the interplay of social life, from politics to industry, work to recreation, with the great biogeochemical, water and energy circulations is often termed *human ecology*. That interplay is where the causes and consequences of global environmental change arise. Its analysis requires an integrated science that looks at the world as it really is. The task in this volume of the Encyclopedia is therefore to provide, or report upon, some of the key aspects of human knowledge that are required for that integrated science.

Editor of Volume Three

Human Disturbance of the Earth System: Dynamics and Complexities

IAN DOUGLAS

University of Manchester, Manchester, UK

The Earth System is dynamic, constantly changing, even though much of the system changes so slowly compared with human life spans that it appears to be permanent and stable. Other geophysical events, like volcanic eruptions, earthquakes, hurricanes and floods, produce rapid changes. Human activity accelerates natural processes, but also alters ecosystems, either through direct actions such as land clearance, drainage, excavation of minerals or dumping of waste, or through gradual indirect impacts such as the effects of acid rain on forests. In these ways, human action has already seriously disturbed Earth surface systems. Any future greenhouse gas-induced changes will be superimposed on other anthropogenic changes to the planet, so compounding them. Earth s ecosystems have an intrinsic resilience, but in many places that resilience is being outstretched by the magnitude of human activity. In some environmental systems, it is now difficult to be sure what their natural pre-disturbance condition was like. Even remote lakes in Canada and northwest Europe have had their pH levels reduced since the time of the Industrial Revolution, often crossing a critical biological threshold at around pH 5.5 in the process.

Land use and land cover change and global environmental change are part of a complex and interactive system in which human action and decision-making lead to changes in ecosystems and soils which produce environmental feed backs that, in turn, alter other ecosystems and eventually feed back on other human activities. These linkages and interactions occur at different spatial and temporal scales and are therefore sometimes difficult to interrelate. Any loss of soil nutrients, for example, has immediate impacts on land productivity, vegetation changes and soil erosion, then mid-term impacts on landscape fragmentation and land productivity, and possible long-term impacts on climate change.

Environmental change is driven by many factors, including economic growth, population growth and movements, urbanization, transportation, and war. Agricultural intensification, industrialization, and rising energy use stand out in terms of their profound impacts on the physical environment and their enormous potential for influencing human health. In the modern world, these three activities are essential for economic development and greater human well-being. Yet, all lead to pressures on the environment, such as pollutant emissions and resource depletion, which in turn can increase human exposure to threats in the environment.

In turn, regional and global environmental changes impact human activities. More extreme climatic conditions can affect a wide range of aspects of human life including crop yields, rangeland regeneration, water supplies for irrigation and domestic consumption, river flows for navigation and fish stocks, weather in tourist resorts, the breeding of disease vectors and sporting activities. Climatic extremes can aggravate local and regional environmental problems, and thus it is helpful to distinguish global change from global environmental problems. Global changes are those that are inherently worldwide in character, and that have to be studied primarily at a global scale. Global environmental problems include large-scale regional phenomena, usually common to several different parts of the world, such as acid rain in North America, Europe and China (Roberts, 1994).

To understand the causes and consequences of global environmental change, it is necessary to think holistically across different time and space scales. People have to be seen as part of the ecosystems or environments in which they live, while it is also recognized that what happens in one place is often governed by decisions taken far away, perhaps on the other side of the world. If a European supermarket chain decides to purchase prawns from a Central American country, the conversion of the local mangrove swamps for is accelerated, perhaps to the detriment of small-scale

local sheries and charcoal making. If a Japanese vehicle manufacturer decides to invest in a brown eld site in an old industrial zone in western Europe, then the biodiversity of exotic and local plants, insects and birds on the derelict site is lost, new drainage of a huge paved and roofed area is required, and a new node of vehicle emissions is created. Environmental change is about hundreds of millions of decisions from individual households to the boardrooms of trans-national corporations and the cabinet rooms of governments. The dynamics and complexities of human disturbance of the Earth System arise from these multi-level, multi-scale decisions.

THE INTEGRATED VIEW: HOLISM AND HUMAN ECOLOGY

In endeavoring to depict a systems view of the Earth, there is a danger of falling between theory and practice. On the one hand, there is a desire to have a robust account of the system, to be able to quantify the components and the linkages amongst them. On the other hand, there is the complexity encountered in practical situations of environmental management, when there are always many stakeholders to be considered and many outcomes from the decision made.

Robust accounting approaches tend to endeavor to simplify cause and effect relationships, for example, by predicting forest clearance from readily gathered variables such as population increase and road building. In reality, what people do to their land is a complex consequence of multiple factors, some external to a household or farm unit and some internal. To improve understanding, knowledge of the biophysical processes operating in the environment has to be brought together with knowledge of how people interpret the environment and make decisions about their behavior, activities and investments. Many people, from the extremes of wealth to the extremes of poverty, are so preoccupied about a range of things, from how much they

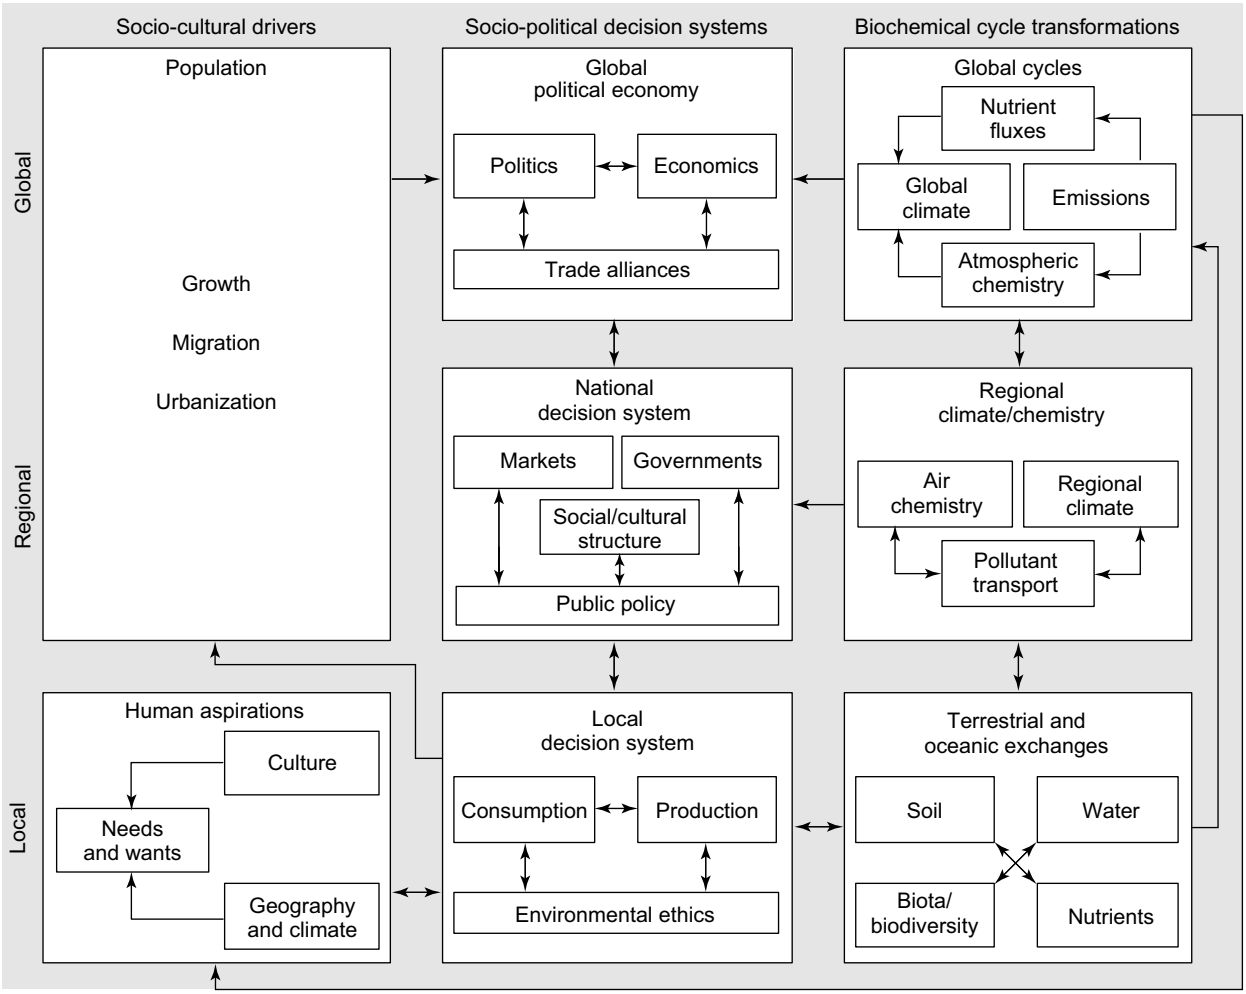

Figure 1 Diagram to illustrate how general human needs and wants are translated into land use changes that in turn affect regional air quality and climate (after Meyer and Turner, 1994)

will lose on the stock exchange in a day to where they are going to find food for their children s next meal, that they do not consciously think about their actions in terms of what they do to ecosystems or the global environment. However, they are all consumers, albeit at different scales, and human consumption, or more strictly diversion and modification of natural biogeochemical cycles, is a major driver of global environmental change.

In Figure 1, human consumption is expressed as population in the large box under studies of social drivers. Human aspirations mediated by culture, and where and how people live, influence human needs and wants. Individual decisions, the micro-decision system, influence land directly and also affect public policy that, in turn, influences the global political economy. The outcomes of decisions at these different levels feed back to the micro-decision system and influence what people do to their land and ecosystems. Thus, land is modified and biogeochemical cycles are altered.

Biogeochemical cycles embrace the turnover of nutrients and other chemicals at the surface of the earth, between the atmosphere, hydrosphere, lithosphere and biosphere. They are the sum of the processes that make ecosystems what they are at a particular place and time. These processes will continue, whatever astronomical, geophysical, biological and people-driven events do to the Earth, but their nature is constantly being modified. People s needs are met by changing those biogeochemical cycles, diverting substances along new pathways, transforming them and creating by-products that are often termed waste, but that have potential uses. That transformation requires energy that, in turn, involves either the extraction of hydrocarbons or coal, or the installation of facilities to exploit renewable energy. This diversion of earth materials, adjustment of ecosystems, and exploitation of past solar energy inputs, produces releases to the atmosphere, hydrosphere and lithosphere that may adversely affect existing ecosystems and cumulatively add up to changes in local, regional and global climate. Gradually, wetlands, lakes and rivers, and eventually coastal and enclosed seas, change their chemical and biotic character. Exploitation of marine resources adds to the global nature of this human impact. Eventually resources that had supported local economies for centuries, such as the cod fisheries of the Newfoundland Grand Banks and the North Sea, become exhausted.

None of these causes of change is isolated from some others. The causes interact with one another. They have to be seen as parts of a whole Earth system that is changing and producing feedbacks and responses; some readily expected and others less anticipated; some taking place where the changes have occurred, such as subsidence above mine workings, others far away, such as the effects of acid rain created by industrial emissions in one place on lakes and rivers hundreds of kilometers away.

To unravel these interactions, feedbacks and responsibilities, holistic thinking is required. Ecology helps in developing this by looking at organisms in their habitat, and their interactions with other organisms and their environment. The extension of ecology from the study of plants and animals in specific habitats to the study of interactions between people, other organisms and their environment requires the inclusion of social processes and introduced the concept of *human ecology*. Early in the 21st century, several varieties of human ecology have emerged. For some, it is primarily concerned with people s interactions with the built environment, while others consider it to be about how the human being, as an organism, responds to environmental stresses and changes and thus suffers disease or retains good health. A third view examines the way society and communities can manage their surroundings to achieve a better life while not over-exploiting natural resources. Whatever the precise definition of human ecology, it is the analysis of the interplay of social life, from politics to industry, football games and lotteries, with the biogeochemical, water and energy circulations that maintain all life on earth. That interplay is where the causes and consequence of global environmental change arise. Its analysis requires an integrated science that looks at the world as it really is. The task in this volume of the encyclopedia is therefore to provide, or report upon, some of the key aspects of human knowledge that are required for that integrated science.

TOOLS FOR THE INTEGRATED VIEW OF ENVIRONMENT AND SOCIETY

Some of the most challenging problems on Earth lie at the interface between the natural system and the human scene (Orme, 1985). Organizing science to tackle this interface is not always easy. Many reports or environmental impact statements dealing with specific people environment issues end up as simply a set of comments on air, water, soils, biota, cultural heritage, employment and society. Matrices, such as the Leopold matrix used in environmental impact assessment (Leopold *et al.*, 1971), provide a way of classifying how one component of an environmental issue affects another. Application of the ranking scheme within the Leopold matrix helps to assess the relative importance of different interactions. However, critics argue that the Leopold matrix is of little value for evaluating overall and cumulative beneficial or harmful impacts or for comparing alternative developments (Barrow, 1997). Later analysts suggested that global and regional environmental changes are the product of cumulative impacts, both beneficial and harmful (Rees, 1995). Analysis of these cumulative changes requires consideration of the sources of cumulative environmental change, the pathways of cumulative change and the cumulative effects. Tables of

Table 1 Types of cumulative effects of human impacts on the environment (after Spaling, 1994)

Type	Main characteristics	Example
Time crowding	Frequent and repetitive impacts on an environmental system	Forest selective logging at a rate exceeding the regeneration rate
Time lags	Delayed impacts	Chemical time bombs
Space crowding	High spatial density of impacts on an environmental system	Transfer of agrochemical residues to groundwater from non-point sources
Trans-boundary movement	Impacts occur downwind, downstream and away from source	Damage to coastal mangroves by polluted sediment washed down by rivers
Fragmentation	Changes in land cover	Isolation of forest remnants; disrupting fish runs by dam and weir construction
Compounding effects	Effects arising from multiple sources or pathways	Complex biogeochemical changes in lakes resulting from inputs by different inflowing rivers
Indirect effects	Secondary impacts	Landslides triggered by earthquakes resulting from the creation of large reservoirs
Triggers and thresholds	Fundamental changes in system behavior or structure	Change of a river from meandering to braided state due to increased flows of water and sediment from major construction sites

different types of cumulative effects (Table 1) help in this process.

Most of the direct impacts on the global environment show the effects of time crowding and space crowding, through repeated actions altering biogeochemical cycles, such as emissions of gases, applications of fertilizer, logging of forests and fishing the same area of ocean repeatedly. Trans-boundary movements detach the causers of local and regional problems from their zones of impact, as with the effects of acid rain on lakes and rivers in countries other than those responsible for the bulk of the release of sulfur to the atmosphere. Time lags and indirect effects can be particularly significant for future generations and are a most important element in the analysis of environmental change.

Energy Fluxes, Materials Flow and Industrial Metabolism

A stimulating approach to the analysis of people environment interactions is provided by the interpretation of ecosystems as open energy systems, using energy circuit diagrams to present energy flows and storages in both ecological and social systems (Odum, 1971, 1972). Such diagrams can be used to illustrate the flows of materials between cities and their hinterlands (Figure 2) and to identify where the biogeochemical cycles involved fail to re-use substances and the relative rates of losses and storage in natural and social systems (Douglas, 1983). The principle behind such analyses is that we should be able to fully account for the paths and sinks of all chemical residues from human activities, particularly industrial processing and subsequent domestic use. It makes sense to process and reuse concentrated materials in wastes, whereas the dilute wastes may be returned to the global biogeochemical cycles in ways that promote productivity and are not toxic (Odum *et al.*, 2000).

Accounting for these changes in energy fluxes and materials flows can be assisted by Odum s concept of emergy (*see* Emergy, Volume 3). Since work is required to concentrate materials, higher concentrations of minerals have greater emergy. For example, in nature, this increase in emergy occurs as minerals are concentrated during the earth movements that create high temperature liquid melts during mountain building events. In industrial ecology (*see* Industrial and Anthroposystem Metabolism, Volume 3), emergy increases as minerals are mined, processed and transformed into other products, e.g., lead into electrical storage batteries. Such an approach has been applied to the analysis of materials flows between the environment and society in Taiwan (Huang, 1998).

Urban metabolism (Wolman, 1965), industrial metabolism (*see* Industrial and Anthroposystem Metabolism, Volume 3), life cycle analysis and materials flow analysis are all techniques for looking at the movement of substances through complex human ecosystems. They help to quantify what happens to materials in the industrial, economic and social sectors, and to facilitate the recognition of

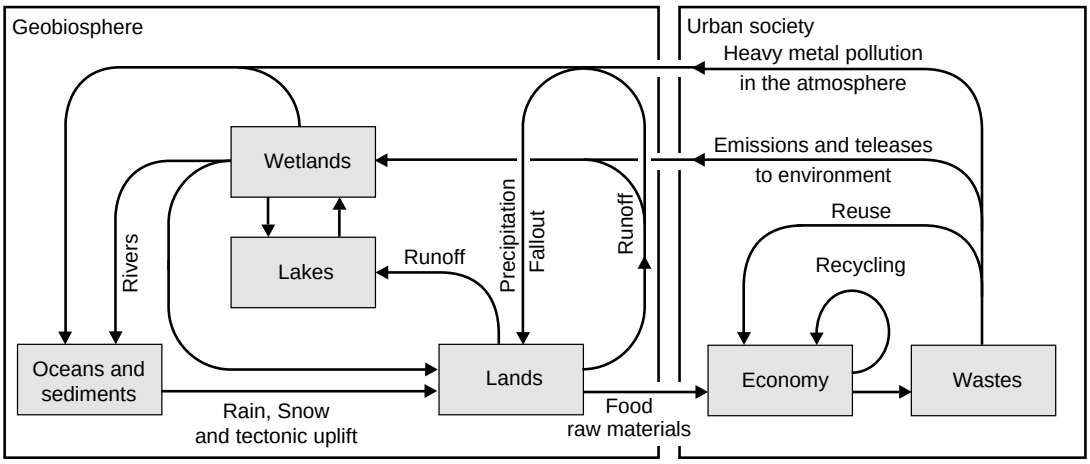

Figure 2 Diagram to show the relationship between the Earth System (geobiosphere, left hand box) and the social system (right hand box). The pathways indicate the extraction of minerals from the Earth and their transfer into the industrial system, the stocking of wastes (tank symbol) and the recycling of residues back to the Earth System, including wetlands, with release of pollutant aerosols to the atmosphere (after Odum *et al.*, 2000)

waste streams that have the potential to be used as resources elsewhere. Development of understanding of sources of emissions and pollutants through these analyses helps bring greater understanding of what might be done to mitigate some of the impacts of the human drivers of global environmental change.

THE HUMAN DRIVERS OF GLOBAL ENVIRONMENTAL CHANGE

Population and human aspirations (Figure 1) encapsulate a range of human driving forces affected by the socio-economic and political decision-making systems that lead to manipulations of the biophysical conditions of the land. These might be clearance of forests to increase grazing land for cattle, excavation of ancient river deposits to nd alluvial gold, or lling in a coastal wetland to extend an airport runway. All actions of this type change the quality and quantity of the local biogeochemical cycles and cumulatively lead to global environmental changes. The magnitude, nature and direction of these changes depend on the pre-existing environmental conditions and ecosystem states.

In broad terms, these driving forces can be clustered in two major groups: those concerned with land cover and land use change (*see* **Global land cover and land use trends and changes**, Volume 3) and those concerned with industrial metabolism (*see* **Industrial and Anthroposystem Metabolism**, Volume 3). These drivers give rise to complex response mechanisms, giving either positive or negative feedback.

Land Cover and Land Use Change

Land cover change and intensi cation of agriculture are essential for producing more food but, when not well managed, create substantial risks, such as exposing workers and communities to toxic pesticides, contaminating groundwater supplies and creating pesticide-resistant pests. Land clearing, irrigation and dams can bring increases in vector-borne diseases such as malaria and schistosomiasis, both of which exact a huge toll in rural areas of the developing world.

Industrial Metabolism

Industrialization fosters economic growth, and with its associated urbanization, usually leads to major improvements in human health. Yet, along with rising standards of living at least for a majority of the population industrialization often means increased exposure to heavy metals, persistent chemicals such as polychlorinated biphenyls, and other toxic chemicals. This is especially true for workers and the poor who often live close to factories. Such exposures are likely to be increasingly pronounced in the developing world, where the most rapid industrialization is occurring.

Rising energy use (http://www.wri.org/wr-98-99/002-ener.htm) is needed to fuel industrial growth but brings many attendant problems. Local air pollution from industrial and vehicle emissions has proved dif cult to manage even in developed economies. Emissions from both fossil fuel use and biomass fuel burning contribute to greenhouse gases (*see* **Biomass Burning in Rural Homes in Tropical Areas**, Volume 3; **Low Concentration Methane Bearing Gases**, Volume 3), with a predicted range of health impacts from severe storms, to drought, to ooding, to an increase in insect-borne diseases such as malaria. Energy demand, which is already huge in the developed countries, is rising fastest in the developing world.

Links Between Land Cover, Land Use and Industrial Metabolism

Trends in the human drivers of global environmental change rarely occur in isolation. Rising energy use, for instance, is part and parcel of industrialization and agriculture. The effects of industrialization are often difficult to disentangle from those of urbanization. Many of the human health effects of these trends are well known and predictable (e.g., increased air pollution that accompanies rising use of fossil fuels, or exposure to toxic chemicals through improper disposal of industrial wastes). Others, however, are far less certain, though potentially large, such as those associated with global climate change and wide-scale ecological disruption (*see* Environmental Change and Human Health: Extending the Sustainability Agenda, Volume 3).

As soon as these impacts of human driving forces on the environment and on the global climate begin to be examined in depth, it becomes clear that changes in the environment can affect health in indirect and often unexpected ways through the disruption of local or global ecosystems. For example, soil erosion stemming from poor agricultural practices can result in reduced crop yields; this could have important consequences for nutrition. Farm animal wastes in the eastern US are believed to cause toxic algal blooms, leading to massive fish kills and potential harm to humans. Note also the recent e-coli outbreak in the Walkerton (Canada) water supply that caused several deaths and many illnesses. Even well-intended development projects can have unexpected outcomes, as occurred in Africa s Senegal River Valley, where the construction of two dams set off a cascade of events that ultimately contributed to nutritional problems for the population and a dramatic increase in schistosomiasis.

CAUSES AND CONSEQUENCES, DECISION SYSTEMS AND CULTURAL ATTITUDES

An alternative way of considering these driving forces is to examine themes in Volumes 3, 4 and 5 of this encyclopedia. Volume 3 is concerned with energy and material flows, food supplies, and the demands and impacts of cities and all other human settlements. Volume 4 looks at environmental management and policy responses, while Volume 5 considers attitudes to the environment, including understanding of how different societies and their governments relate to the environment.

Volume 3 takes the biogeochemical cycles elaborated in Volume 2 and examines how they are modified by human-driven energy and materials flows. Food production and consumption are directly related to land cover, land use and biodiversity issues, and the major impact on the environment throughout the food production, processing, transport, consumption, and waste cycle (*see* Food Consumption Patterns and their Influence on Greenhouse Gas Emissions, Volume 3). Cities are where people are most concentrated and have most modified the surface of the earth, but their demands affect other ecosystems, both nearby and in other parts of the world (*see* Urban Ecosystems, Volume 3). In these cities, in new high technology parks, and among home-workers, evolving technologies transform lives and facilitate decision-making. Modern information technology, from remote sensing to mobile phones, helps both to hasten exploitation of environmental resources and to monitor and police environmental degradation and environmental protection legislation.

Information and Communication as Driving Forces

Developments in information and communication are now major driving forces in societal transformation and have important implications for the global environment. Information technology has three benefits for society and industry by: (1) compressing time; (2) overcoming geography; and (3) altering the structure of relationships, such as bypassing intermediaries. For transnational corporations, this means greater efficiency and effectiveness and facilitates innovation, quality improvements and the penetration of new markets. The manufacturing plants of Volkswagen AG in the Czech Republic, China, Mexico, Spain and elsewhere are linked by satellite connections to the company headquarters in Wolfsburg, Germany, enabling the company to bypass incompatible and costly national telecommunications networks (Malecki, 1997). Taking advantage of the modern telecommunications and information technology, many businesses have shifted research and development and data processing activities to localities where labor and land costs are low. India has a large high technology complex in Bangalore to which firms from the US, Singapore and the UK have sub-contracted work in electronics, software and data processing. Information and communication technology thus alters locations of economic activity, promoting urban development and consequent environmental changes in places where they had not occurred before.

Technology and communications can have both environmental benefits and examples of social inequity. Canon s global center for recycling and refurbishing laser printer tone cartridges is in Dalian, China. While the recycling is good for the global environment, the location of these dirty jobs in China reinforces the spatial division of labor that increasingly puts low paid, less healthy jobs in the poorer countries (Shrivastava, 1995). Another side of this coin is that telecommunications and modern air traffic permit agribusiness to produce seasonal crops in appropriate places around the world at any time of the year, and supply supermarkets in the wealthy countries with commodities like grapes and cherries continuously. The growth of this business has driven many land use changes, particularly in

tropical highlands of countries like Colombia and Kenya. Information and communications are thus facilitating more dispersed, more rapid environmental changes than would otherwise occur.

Macro Decision-making and the Global Political Economy

Decisions by governments, both in individual states and through international agreements and organizations such as the World Trade Organization (*see* WTO (World Trade Organization), Volume 4) and the Intergovernmental Panel on Climate Change (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4), can effect changes in driving forces and exert influence over people s relationship with the environment. Policies such as the European Union s (EU s) Water Framework Directive can help reverse environmental trends by ensuring that participating governments take action to (in the Water Framework Directive s case)

> prevent further deterioration and protect and enhance the status of aquatic ecosystems and, with regard to their water needs, terrestrial ecosystems and wetlands directly depending on the aquatic ecosystems; and to promote sustainable water use based on a long-term protection of available water resources.
>
> (European Union, 2000)

Agricultural subsidies are a major influence on land use, changes in national government policies quickly altering inputs of fertilizer and forms of land management (*see* Agricultural Subsidies and Environmental Change, Volume 3).

PATTERNS OF CAUSES AND CONSEQUENCES OF GLOBAL ENVIRONMENTAL CHANGE

Several themes relating to the human drivers of environmental change are developed in this volume. Overall, they derive from population growth and associated changes in human settlements. Conversion of the Earth s surface results from the effects of agriculture, biomass burning, deforestation and logging, deliberate earth moving activities including mining and quarrying, and the growth of tourism and recreation. The use of fossil fuels in industry, machinery and transportation drive a wide range of environment changes. Water resource use creates many changes to river systems and wetlands. Fish production, both by fishing and by aquaculture, introduces major ecosystem changes. Urban expansion, urban materials use, waste dumping and transport exert interrelated impacts on ecosystems and are vulnerable to climate changes. Modifications to the pathways of particular chemicals also require attention.

Land Cover Conversion and Land Use Change

Land cover change to increase cropland dominated ecosystem change from 1700 to the mid-1980s. Cropland increased globally by 392 to 466%, depending on the means of estimation, expanding from an area roughly the size of Argentina to that of the South American continent. It grew at the expense of forest, grassland, and wetlands. Change accelerated globally, in terms of both the conversion of lands to cultivation and of the intensification of agriculture on land already cultivated. The net global area of irrigated cropland has increased by 2400% since 1800, from $80\,000\,km^2$ to $2\,000\,000\,km^2$. Today, cropland conversion and perhaps intensification are most rapid in the less industrialized portions of the world, while the area of cropland has decreased in Europe (*see* Global land cover and land use trends and changes, Volume 3). The total area of all sorts of grassland has changed little sine 1700, perhaps a net global decline of 1%, as its loss to cropland (primarily in Europe, North America, and Southeast Asia) has been compensated by its gain from forested land (mostly in Africa and Latin America). During the next decade and century, agriculture will shift from expansion towards intensification (*see* Green Revolution, Volume 3), while urban areas, particularly along continental margins, will continue to grow. By the end of this century, most of the world s land area will be intensively and formally managed, and open lands will no longer exist. Furthermore, local atmospheric pollution will affect much of world s prime agricultural lands.

Since pre-agricultural times, worldwide forest/woodland/tree cover has diminished by about 15%, but the size of this figure depends on how precisely woody vegetation is defined as forest or woodland. Currently, considerable afforestation is occurring in Europe and North America, as land is taken out of cultivation (*see* Afforestation: Environmental Impacts, Volume 3), while large-scale tropical deforestation is occurring because of logging, cultivation, and livestock uses (*see* Deforestation and Habitat Fragmentation in the Amazon Basin, Volume 3).

Shifts of Earth Surface Materials: Mining, Quarrying and Construction

The materials flows due to mining and urbanization dominate the human transformation of the Earth s surface and directly link industrial activity to the sustainable use of resources. The total mass of material moved is approximately three times the amount of mineral matter actually entering processing streams and globally exceeds the mass of sediment transferred from the continents to the world s oceans by rivers (*see* Materials Flows for Mining and Quarrying, Volume 3). Mining and quarrying create new landforms as they remove hillsides and even mountain ridge crests, create holes in valley floors and amass spoil heaps (*see* Geomorphological Change for Urbanization

and Industry, Volume 3). These landscape changes are sometimes used creatively to provide facilities for tourism, from artificial ski slopes in urban areas, to resorts and golf courses built by landscaping hillsides or reclaiming land from the sea (*see* Geomorphological Change: Landscape Modi cation for Recreation, Volume 3).

Fossil Fuel Use

Global energy production in 1993 reached 338 exajoules (1 exajoule • 10^{18} joules, equivalent to about 163 million barrels of oil), 40% more than in 1973. However, energy use is extremely uneven, the *per capita* consumption in the US is five times the world average, that of western Europe three times, and that of sub-Saharan Africa only one-tenth the world average. This is reflected in the pattern of *per capita* carbon dioxide (CO_2) emissions among the countries of the world (*see* National Responsibilities for Greenhouse Gas Emissions, Volume 3). Nuclear power offers a solution to the greenhouse gas problem, but has major difficulties for radioactive waste disposal and reactor safety (*see* Chernobyl, Volume 3; Nuclear Waste: Geological Issues, Volume 3). Most people in the world s poorest countries depend on wood fuel, with over 80% of forest cutting in many countries being used to produce fuel. Already forests are being cut to make charcoal for consumption in towns and cities hundreds of kilometers from the centers where it is used (*see* Biomass Use for Urban Fuels in Developing Countries, Volume 3). During the 21st century, those sources of wood will largely be used up. Countries will have to aim at alternative fuel sources, as well as encouraging agroforestry to promote cultivation of fuel wood. This biomass burning contributes to greenhouse gases, just as fossil fuel use does. However, future shortages of wood will help drive urban and rural electrification schemes forward, based where people have access to fossil fuel use, or to nuclear energy. Each of these alternatives has large environmental change feedbacks.

Fossil fuel consumption is driven by increase in wealth: the wealthiest people use the most energy. Motor vehicle ownership is one index of wealth. In 1993, private car ownership ranged from 1.48 $1000^{\bullet 1}$ in China to 3.1 in south Asia, and 561 in the US. However, since 1993, passenger car ownership has increased rapidly in many Asian countries, growing 17% $yr^{\bullet 1}$ in India. Predictions are that the number of motor vehicles in the world will have risen from 250 million in 1970 to over 800 million by 2010 (World Resources Institute, 1996). The materials flows involved in making all those cars, disposing of those that are worn out, and supplying fuel for them are major social drivers of global environmental change. Despite improvements in the fuel consumption and energy efficiency of motor vehicles, the sheer growth in their numbers maintains the level of their collective environmental impact, but the global location of growth of that impact is shifting towards the great cities of Asia and Latin America. Indeed, a simulation model has projected that by 2025, 10 35% of the world s grain production could be at risk from increasing frequencies and intensities of ground-level ozone episodes caused by the sheer growth in the motor vehicle population (Chamiedes *et al.*, 1994).

Water Resource Use

Water supplies for agriculture and the demands of irrigators are already critical elements of the land use dynamics in regions such as West Asia and semi-arid Africa. Agriculture accounts for as much as 70 80% of water use worldwide and competition for water from other economic and social activities is growing as countries develop. In some countries, nearly all the cropland depends on irrigation, e.g., 100% of that in Egypt, 78% of that in Pakistan 78%, and 47% of that in China and Iraq 47%, compared to a world average of 16%. Irrigation has major impacts on biogeochemical cycles, on soil conditions and on energy consumption (*see* Irrigation: Environmental Impacts, Volume 3). In some cases, the reservoirs storing irrigation water even cause minor earthquakes (*see* Earthquakes Triggered by Human Activities, Volume 3). Changes to the quantities of water available and to the quality of that water are both significant for future water resource management. Reuse of water along major rivers in every continent is threatened by deteriorating water quality, from agricultural pollution as well as urbanization and industry (*see* Nitrogen: Agricultural Uses and their Impacts, Volume 3). Efforts in old industrial areas, even in Manchester, UK, the home of the industrial revolution, have brought fish back to formerly polluted rivers. However, for every kilometer of river so improved, there are probably tens of kilometers of rivers elsewhere in the world being contaminated by effluents from new industries, inputs of agricultural chemical residues, runoff from parking lots or by the sediment washed into streams as new land is cleared for agriculture or housing. Water is already perceived as a potential flash point for international conflict (Libiszewski, 1999), which, in turn, would cause further environmental damage (*see* Environmental Changes Driven by Civil Conflict and War, Volume 3). Efforts to manage water in the future will have major implications for land use/cover change. Policies affecting the mechanisms of water distribution and use (institutions, water rights and pricing mechanisms) will play a key role. In addition, changes in precipitation regimes and in land cover, especially through deforestation, will aggravate water resource problems. Water issues are primarily those of dealing with the consequence of global environmental change, but the actual ways water is used contribute to local and regional changes, particularly the eutrophication of lakes and wetlands (*see* Eutrophication, Volume 2;

Circulating Freshwater: Crucial Link between Climate, Land, Ecosystems, and Humanity, Volume 5).

Fisheries and Aquaculture: Marine Ecosystems

For most of human history, the oceans were part of the global commons, in the sense that theoretically anyone could fish anywhere. Today, countries have exclusive economic zones, within which fishing may be regulated, but many of the major commercial fish, including cod, herring, salmon and tuna, migrate across zone borders and thus stocks are difficult to manage on a global basis. New technologies, especially gill nets, and large and powerful fishing fleets have resulted in depletion of the total stock, just as excessive logging overexploits the timber stock. The hunting of whales illustrates the issues of exploitation of marine life particularly harshly because of the impacts of technological innovation and the sheer scale of the slaughter around the world. The whaling industry acted as though the oceans were an inexhaustible resource, creating a real tragedy of the commons. International agreements regulating whaling remain difficult to police (*see* **Marine Mammal Exploitation: Whales and Whaling**, Volume 3). Aquaculture aims to replace some of the sh caught in the wild, but it has its own set of environmental and ecological impacts, with some serious implications for the transmission of disease from farmed stocks to wild stocks (*see* **Aquaculture: Salmon Farming**, Volume 3). Conversion of wetlands for aquaculture has had major effects on many mangrove ecosystems (*see* **Aquaculture in Asia**, Volume 3).

Urbanization as a Driver of Environmental Change

The increasing urbanization of the world population has triggered major changes in land use and land cover, and in the consumption of materials and food from the land and the oceans. The social factors linked to urbanization, particularly rural urban migration, feed back to environmental change as people abandon farms, or husbands go off to the city, while wives struggle to both raise children and till the land. In other situations, people who work in cities become commuters from country villages, and farmland becomes much more valuable as building sites. As indicated earlier, urban demands greatly manipulate biogeochemical cycles.

Analysis of biogeochemical cycling can be extended to incorporate an urban, or industrial, system in which the urban fabric is a repository of substances, alongside the lithosphere, biosphere, hydrosphere and atmosphere (Odum, 1971; Douglas, 1983) (*see* **Anthropogenic Metabolism and Environmental Legacies**, Volume 3). Indeed, the urban fabric is constantly being renewed, demolition creating a recycling opportunity for crushed concrete to be used as aggregate. The urban fabric can thus be interpreted as the urban deposit (Wilburn and Goonan, 1998), a form of renewable resource, constantly being restocked with new structures. In this way, people s activities are seen as part of the processes changing the Earth s surface at geological scales.

Changes to the Pathways of Particular Chemicals

Human use of materials has greatly modi ed the ows and stocks of key elements. Intensi cation of agriculture has led to great growth in the application of fertilizers to a world average level of 97 kg ha$^{\bullet 1}$ in 1996 1997 (World Resources Institute, 2000), ranging from extremely low quantities in countries like Namibia and Rwanda to 1475 kg ha$^{\bullet 1}$ in Belgium, 821 kg ha$^{\bullet 1}$ in the Netherlands and 693 kg ha$^{\bullet 1}$ in Korea. Pesticide use involves a far higher mass; data are not available for all countries, but the published range is from 1 kg ha$^{\bullet 1}$ in countries like Afghanistan and Burkino Faso to 19 288 kg ha$^{\bullet 1}$ in Italy and 13 829 kg ha$^{\bullet 1}$ in Korea. These agricultural chemical transfers are, in part, replacing the nutrients removed from the soil during harvesting. Some of those nutrients may be returned to the soil as sewage sludge. However, some are leached out, enter other food chains and contribute to major ecosystem changes and eutrophication of water bodies (*see* **Nitrogen: Agricultural Uses and their Impacts**, Volume 3).

Nitrogen is a key chemical in the agricultural system. Methane emission from agricultural activities is another (*see* **Cattle Grazing: Impacts on Land Cover and Methane Emissions**, Volume 3). Carbon is involved in all human activities, while sulfur has been particularly associated with fossil fuel combustion. Emissions of these substances have changed through time (*see* **Trends in Global Emmisions: Carbon, Sulfur, and Nitrogen**, Volume 3). Their impacts are now pervasive, with acid rain around industrial zones now affecting wide continental areas, and nitrate contamination of groundwater supplies widespread. Attention to sources and pathways of these and other elements can provide the means of identifying their fates and how their impacts may be modi ed. Establishing ow diagrams and developing good predictive models helps to identify where industrial and agricultural chemical use can be modi ed to achieve greater ef ciency, more recycling, less waste and lower levels of environmental impact.

FEEDBACKS IN THE SOCIETY: ENVIRONMENT SYSTEM

Figures 1 and 2 indicate links running in both directions between the earth system, with its biogeochemical cycles, and the social systems. These feedbacks always occur. However, often the relationships between economic activities and biogeochemical circulations are not immediately

evident. Nevertheless, there are important connections from the impacts of both direct and hidden flows of materials on the environment and the subsequent feedback from those impacts to the economy. In Europe, the River Rhine provides several examples of these feedbacks between economic materials flows and geological processes at the surface of the earth. In the Swiss upper reaches, the Jura water connection to improve navigation caused such changes to the stability of the channels that a second set of engineering works had to be undertaken to remedy the impacts of the first. In the Rhine Rift Valley, the river is canalized, but flows so swiftly that it scours its bed. A large, continuous gravel replenishment operation, involving a materials flow of gravel from the floodplain into the rectified channel, is necessary to maintain the equilibrium of the channel. At a smaller scale in Britain, canalization of the River Mersey through the south of Manchester has caused severe bank erosion downstream of the rectified section which has led to large expenditure in relocating electricity pylons to avoid undermining by the river.

Biophysical feedbacks play a critical role in long-term dynamics of land use and land cover, but there is little agreement on their strength or temporal and spatial scales. For example, some say that soil erosion losses and their implications for long-term agricultural productivity and land cover change may have been overestimated. The United Nations estimates of desertification and erosion of global soils may be too high and the economic risks of soil loss may be exaggerated (*see* Desertification, Definition of, Volume 3). Despite observations indicating that overgrazing in parts of Africa would shortly destroy the landscape for that activity, other assessments considering traditional management practices, local soil conditions, and patterns of soil erosion and deposition suggest that widespread land cover degradation and change at the sub-continental scale may be 100 or more years away, although this does not mean that there is no ecological degradation. Scale is important here. Local soil degradation matters greatly to local people, directly affecting their livelihoods, but it may not be extensive enough to cause, for example, a sufficiently large change in surface albedo to contribute significantly to climate change at the global scale.

Many feedbacks occur long after the event that caused them. These delayed impacts, such as the arrival of nitrate in spring water 10 or more years after it was applied on the land surface above the aquifer, or the transfer of salt from the hill slopes to the valley bottoms decades after land clearance, can be insidious and long lasting, being spatially and temporally removed from their causes (*see* Salinity and Agriculture, Volume 3). In many ways such local consequences have a parallel in the ozone holes over Polar Regions; they are delayed stratospheric responses to cumulative actions at the surface of the Earth.

CONCLUSION

The Earth System operates through a series of temporary equilibrium states, in which ecological relationships tend to be stable for several years, decades or centuries. Natural climatic oscillations, particularly those of the Quaternary period, have left legacies that are only marginally stable under present-day conditions. Thus, although sea level is now rising, some areas, such as Scandinavia and the Hudson Bay lowlands, are rising faster than the sea level through isostatic rebound following the retreat of the great ice sheets of the last Ice Age. On the desert margins, fossil sand dunes are held in position by their natural vegetation. Once the precarious vegetation cover is removed, the underlying sands can be remobilized. Thus, some ecosystems, some vegetation soil landform combinations, are more vulnerable to change than others. Thus, in places, once the human driving forces come into play, environmental change is rapid. Other ecosystems have a greater resilience, some sustaining a high level of intensive agriculture for long periods (*see* Agricultural Intensification in Java, Volume 3).

To understand what is happening at present and predict what might happen in the future, understanding of both the biogeochemical cycles on which individual ecosystems depend and the human driving forces altering those ecosystems is required. Both robust accounting systems and holistic thinking are required. Theoretical diagrams and the detailed analysis of case studies help in learning what might happen and what has happened.

The themes outlined in this essay indicate the types of interrelationships, causes, consequences and feedbacks involved in environmental change. The articles in this volume provide frameworks, accounts and examples of what has happened and what might happen. They indicate responsibilities for environmental change and its consequences at the individual, community, national and international levels. They show the contributions science has made to specific issues and the way that environmental policies could be improved or better enforced to alleviate some of the impacts of environmental change. If people see themselves as part of the great Earth system, as actors in the great drama of environmental change, they may appreciate that their individual and collective roles, however small, are as vital a part of planetary human ecology as the ants in the soil, the dung beetle in the forest, the operators of bulldozers and the presidents of transnational corporations and nation states. The challenge is to realize that we are all responsible, and that we can all do something. This encyclopedia sums up what we know, what we need to know and what we must do.

Global land cover and land use trends and changes

IAN DOUGLAS

University of Manchester, Manchester, UK

Land cover and land use changes may be grouped into two broad categories: conversion or modi cation. Conversion refers to change from one cover type to another, such as the conversion of forest to pasture. Modi cation involves the maintenance of a broad cover or use type while changes take place in its structure or function, as happens when a forest is selectively logged and its canopy characteristics are greatly altered.

*For the Earth's land surface, land use and land cover changes are going to continue to be the most important component of global change, at least for several more decades (*see ***IGBP Core Projects****, Volume 2). The world has some 130.5 million km^2 of land. Present land cover is about 34.5 million km^2 of forest (World Resources Institute, 2000), 26.9 million km^2 grassland and 20.7 million km^2 cropland of all forms (Table 1). Thus agricultural activities (de ned as arable, pasture, and marginal land use) currently occupy approximately 37% of the earth's land surface. Urban and mining activities probably cover only around 1%. The remainder includes barren and steep terrain, including glaciers and mountain summits largely devoid of vegetation and unsuitable for agricultural activity.*

Up to and including most of the 20th century, agricultural output was increased mainly by bringing more land into production by converting forested and natural grassland areas to cultivated land. The limits of geographic expansion were reached many years ago in densely populated parts of India, China, Java, Egypt and Western Europe. Nevertheless, the total area of land used for agriculture rose from 45.5 million km^2 in 1966 to 49.3 million km^2 in 1996. This global average 9% increase in agricultural land is unevenly distributed. In the industrialized countries, the agricultural area increased by only 2.9% in those 30 years, but in the developing countries, it grew by 15.4%.

INCREASES IN AGRICULTURAL LAND

Among the countries with over 20 000 km^2 of cropland where the increase in agricultural area exceeded 25% between 1983 and 1993 are Egypt (26.5%), Mali (25.1%), Nicaragua (55.6%), Malaysia (46.6%) and Saudi Arabia (46.6%). The role of irrigation is outstanding in the Egyptian and Saudi Arabian cases, but generally irrigation is used to intensify production on existing land (*see* Irrigation: Environmental Impacts, Volume 3). In Asia particularly, intensification of production, obtaining more output from a given area of agricultural land, has been achieved primarily through producing multiple crops each year in irrigated agroecosystems using new, short duration crop varieties (*see* Agroforestry, Volume 3). The global irrigated area grew by more than 70% from 1966 1996. While irrigation is used on only 5.4% of agricultural land globally, it supplies 35% of cropland in South Asia, 15% in East Asia, and 7% in South East Asia.

Land abundant developed countries still possess the physical capacity to increase food production significantly. However, because of more intensive use of the existing arable land, and public policies that allow farmers to set-aside a proportion of their land, some 40 million hectares of land have been taken out of agricultural production in the US, Western Europe and Oceania over the last three decades. Cropland in the developed world actually fell by 2.2% between 1987 and 1997, with that of the US and Canada combined falling by 3.9% and that of Europe by 2.4%. The highest individual national cropland decreases over the same decade were in Italy (9.5%), the UK (8.3%), Romania (7.4%), Spain (6.0%) and the US (4.7%).

Unlike cropland, forest cover has globally declined, falling by 0.32% per year over the 5 years 1990 1995. The percentage decline is most marked in small countries, such as in Central America and the Caribbean (fall of 1.26% per year), and in countries with few native

Table 1 Estimates of pre-agricultural and late 20th century land areas under major land cover types (pre-agricultural and 1983 after Matthews (1983) and Williams (1997); 1997 estimated from data in World Resources Institute (2000), units • millions km^2

	Pre-agricultural	1983	1997
Forest	46.8	39.3	36.5
Wood	9.7	7.9	7.7
Shrub	16.2	14.8	14.6
Grassland	34	27.4	26.9
Tundra	7.4	7.4	7.4
Desert	15.9	15	15
Cropland	0	17.6	20.6
Urban/mining	0	0.9	1.3
Total land	130	130	130

forests, such as the Middle East and North Africa (fall of 1.00% per year). In contrast Europe (annual gain of 0.06%) and the US and Canada (annual gain of 0.17%) show slight increases in forest cover. Among the countries with more than 50 000 km^2 of forest that experienced an annual decrease in area of over 2% per year are: The Philippines (3.54%), Paraguay (2.65%), Thailand (2.65%), Nicaragua (2.54%) and Malaysia (2.43%). Across the Amazon Basin as a whole in 1986 1992, tropical deforestation was approximately 0.34% per year (*see* **Deforestation and Habitat Fragmentation in the Amazon Basin**, Volume 3).

POSSIBLE FUTURE TRENDS IN LAND USE AND THEIR EFFECTS ON LAND COVER

Total global food demand is expected to increase by 50% by 2015 and by more than 110% by 2050 (UNEP (United Nations Environment Programme), 1997). The combination of the increase in agricultural demands, changes in consumption patterns (less staple foods and more luxury products, which require more inputs), and ongoing technological development in agriculture will lead to a 27% increase of the total agricultural area by 2015 and about a 42% increase by 2050.

In the past, food production rose by both more intensive use of the land and by expansion of the agricultural land area. As in the 1990 2000 decade, the mainstay of agricultural production growth in the future will increase yields through intensi cation, from the application of new varieties and of increasing use of the products of agricultural technology such as fertilizers, irrigation systems and tractors, as well as improvements in management. (Tractor use in the Middle East and North Africa increased by 34% from 1987 1997 and in South America by 14%). The global area of irrigated land increased by over 21% in the ten years to 1997.

Agriculture s share of the total land is projected to increase to 46% by 2015 and to around 50% by 2050, whereas the ratio between pasture and arable lands is expected to remain relatively stable over time. These global changes mask quite distinct regional differences in land use changes. In industrial regions, agricultural land is projected to increase from its 1990 level by about 3% by 2015 and 10% by 2050. In North America, the percentage increase is 4% by 2015 but only 2% by 2050, while in Europe and the former USSR the gures are 4% by 2015 and 18% by 2050.

Developing regions, on the other hand, show a projected increase in agricultural land area of about 33% by 2015 and 45% by 2050 compared with 1990. The lowest increases are expected in Latin America and the Caribbean about 10% by 2015 and 20% by 2050. Because the large populations of South and East Asia have already occupied virtually all the available land suitable for agriculture the increases in Asia and the Paci c are about 28% by 2015 but only 24% by 2050. In Africa and West Asia, increases in agricultural area are projected to be much higher about 55 and 57% by 2015, respectively, and 90 and 95% by 2050. These gures include extensive use of grassland.

The large increases in the area of cultivated land in Africa and West Asia result from the sharp rise in demand already shown by the rate of expansion of cropland in Egypt and Saudi Arabia. The gures assume only moderate developments in agricultural management and technology. In particular, traditional animal husbandry systems, which require considerable grazing land, are expected to be continued. However, the regional expansion in farm mechanisation, indicated by the growth in tractor numbers, may indicate a trend to more elaborate farming systems, with better management but which would lead to far less dramatic land use changes by 2050.

In summary, to meet future food demands, a considerable extension of the area currently used for agriculture is needed, in addition to improvements in yields, unless more drastic changes take place in societies. It is projected that this extension will principally affect developing regions and some parts of North America, Europe, and the former USSR. In all areas, any extension of agricultural area is projected to occur at the expense of remaining natural areas. However, climate change is likely to bring a reduction in harvests in many regions. In the Canadian prairies, for example, drought now occurs on average once every 15 years; but by the end of this century, it could occur once every three years (Paul Slovak, personal communication).

POSSIBLE IMPACTS ON GLOBAL CLIMATE CHANGE

The process of land cover conversion to new uses, such as forest clearance for grazing land or plantation development,

Table 2 Annual net flux of carbon to the atmosphere from land use change: 1850–1990 (after Houghton, 1999), units • Tg C •1 teragram • 10^{12} g • one million tonnes • 1 Mt)

Year	North America	South and Central America	Europe	North Africa and Middle East	Tropical Africa	Former Soviet Union	China	South and South-east Asia	Pacific developed region	Total flux
1850	87.28	42.48	55.04	3.98	5.61	58.56	56.62	85.63	2.05	397.14
1900	158.92	60.36	45.19	17.55	12.56	57.79	47.54	161.44	21.75	583.11
1950	25.97	229.84	24.66	43.16	61.33	13.08	73.72	340.01	34.00	845.77
1990	12.42	577.16	• 18.08	23.24	341.50	20.11	48.69	1094.39	3.92	2103.34

leads to biomass burning and the release of greenhouse gases to the atmosphere. Past trends in such emissions are indicated by careful calculations of the annual net flux of carbon to the atmosphere from land use change (Houghton, 1999) (Table 2). The 18th century agricultural changes and early 19th century rise in European populations produced the highest flux from Europe in 1850. Thereafter the European flux declined until about 1980, when the trend reversed with the forest cover starting to increase and carbon sequestration growing.

The great 19th century agricultural expansion in North America produced a peak flux there by 1900, since when the flux has decreased. In North Africa, China and the Pacific the annual fluxes peaked around 1950. However, in Central and South America, Sub-Saharan Africa, South and South East Asia, the fluxes are increasing, and because of the huge total biomass of their tropical forests, are much greater in magnitude than those of other parts of the world. The predictions of agricultural land expansion suggest most strongly that these annual fluxes will continue to increase at least as rapidly as they did in the period 1950 1990. Thus land cover change will continue to be a major factor in the release of greenhouse gases.

Global Population Trends

WOLFGANG LUTZ AND ANNE GOUJON

International Institute for Applied Systems Analysis (IIASA), Laxenburg, Austria

The 21st century started with a demographic paradox. Fertility in most developing countries declined at rates much faster than the decline experienced in the industrialized countries. Today already more than 60 countries with 44% of the world population have fertility below the so-called replacement level of two children per woman. On the other hand, the world population is still expected to grow strongly, most likely by more than two billion within the next 30 years.

*In this article, we summarize the current demographic situation and discuss projected trends in population growth and aging over the next century based on the most recent projections of the International Institute for Applied Systems Analysis (IIASA) (*see ***IIASA (International Institute for Applied Systems Analysis)****, Volume 4). The paper also draws on O'Neill* et al. *(2001). Our projections indicate that the world population will rise signi cantly from its present level of around 6 billion (Lutz, 1996). On the other hand, it is unlikely to double from its present size and a decline may occur during the second half of the 21st century. The distribution of the population will further tilt from more developed countries (MDCs) to less developed countries (LDCs). Finally, the world population will continue to age: the proportion of the 60• age group in the total population will almost certainly double and will likely triple over the next century.*

WORLD DEMOGRAPHIC TRENDS

Extremely rapid population growth is a relatively new phenomenon. For millennia, the strong fluctuations between birth and death rates cancelled each other, leading to slow population growth. It is in the 17th century that the world population took off, and reached 1 billion after 1800. The second billion was added more than a century later, in 1930. It took only 30 years, until 1960, to add the third billion. The fourth billion was added between 1960 and 1975, and the six billion mark was passed in 1999. In fact, despite the apparent acceleration, both the annual growth rate of world population and the number of persons added each year have passed their peaks and are expected to continue falling. The growth rate peaked at 2.1% year^{-1} in the late 1960s and has since fallen to 1.3% (see Table 1). This does not mean that little additional population growth is to be expected. The world population could rise to 10 12 billion by the end of the 21st century.

The statistics are, however, indicative of the tremendous changes that have taken place over the past four decades. The TFR, defined as the number of children a woman would give birth to if through her lifetime she experienced the set of age-specific fertility rates currently observed, declined with a rapidity that was unimaginable in the 1960s. This decline was very pronounced in some regions, i.e., Asia, Latin America, and North America. For example, in Latin America, the TFR fell by 1.4 children from 1955 1960 to 1975 1980 and again by almost 2 children between 1975 1980 at the turn of the century. One exception to this general decline has been Africa, where fertility rates remained well above six children per woman through the late 1980s; since then, the beginning of a fertility decline has become apparent. Meanwhile, regions like Europe that had already achieved very low fertility by 1975 1980 saw these rates persist or fall even further. In 2000, MDCs (More Developed Countries) have, on average, below replacement fertility levels, but even some major developing countries, most prominently China. Inhabitants of the MDCs on average have fewer children than LDCs (Less Developed Countries): TFR is 1.6 in MDCs versus 3.0 in LDCs.

The spread of modern sanitation and medicine caused infant and child mortality rates to fall, resulting in significant reductions in mortality during the 1950s and 1960s. During the period 1955 1960, life expectancy was lowest in Africa (40 years) and Asia (45 years), but had already increased significantly in Latin America (54 years). *Life expectancy* at birth is the average lifespan implied by the observed age-specific mortality rates in a given year. Over the subsequent 20 years, life expectancy increased impressively in all parts of the world. On average, the

world population gained 10 years between 1955 and 1975. The gain was over 13 years in Asia over this short period, and eight years in Africa. Improvements continued over the next 20 years to 1995 2000 but at a somewhat slower speed, with developing regions all seeing substantial improvements, especially Asia where the life expectancy improved by eight years. Very recently, some African countries seriously affected by the human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) epidemic have seen reversals of this trend. The African continent has, on average, a life expectancy hardly above 51 years. The second lowest figure is Asia with 66 years. Inhabitants of the MDCs on average live significantly longer. Life expectancy at birth for both sexes combined is about 75 years, versus 65 in LDCs.

These trends in fertility and mortality resulted in different patterns of population growth in different parts of the world. The combination of high fertility rates together with declining infant and child mortality led to soaring population growth rates in the 1950s and 1960s in less developed regions. As shown in Table 1, growth rates in 1955 1960 were highest in Latin America because high fertility in the region was associated with already lower infant and child mortality. By 1975 1980, however, the population growth rate in Africa surpassed that in Latin America as Africa s mortality rates fell and fertility rates hovered at about 6.5 children on average per woman. African population growth rates have only recently started to decline; it was 2.4% for the 1995 2000 period.

The demographic contrast is significant between the well-off populations of Europe, North America, and Japan and the poorer populations of Asia, Africa, the Middle East, and Latin America. The population of the MDCs is relatively small (about 1.2 billion in 2000) and is expanding very slowly (0.3% year^{-1}). That of the LDCs is large (about 4.9 billion in 2000) and expanding rapidly (1.6% year^{-1}) after increasing by a factor of 2.1 since 1955. There are two main consequences to this trend:

1. the share of today s industrialized countries in the world population decreased from 30% in 1955 to 20% in 2000 and is likely to decrease much more in the future;
2. the population density has been soaring in the developing world. In 1960, MDCs and LDCs territory were, on average, similarly populated: respectively 17 and 25 inhabitants km^{-2}. In 1980, the density of LDCs was already more than twice that of LDCs and the difference has increased further with the past 20 years.

The population density per square kilometer of Asia, and Oceania doubled in the forty-year period between 1960 and the century end. Asia has by far the highest density of all world regions with 116 inhabitants per sq. kilometer. The European population density has been stagnating around thirty inhabitants, and that of Northern American region is less than 15.

The age pyramids in Figure 1 show how varying demographic experiences in different regions have a strong imprint on the age structures of their populations. Low fertility caused the narrowing of population pyramids at the bottom in MDCs. Extended longevity is the reason for the fattening at the top. This phenomenon of population aging is an important social phenomenon in MDCs, especially in relation to the uncertain future of pension and health care systems and implications for labor markets and the work force (Kinsella and Gist, 1995). Aging has already started in LDCs, and the speed of LDC fertility decline will accentuate the aging phenomenon (*see* Demographic Change: the Aging Population, Volume 3; Demographic transition, Volume 5).

The outstanding demographic event of the last 25 years has been the rapid decline in fertility around the world, particularly in LDCs. All research suggests that fertility decline is complex, regionally differentiated, and context dependent. For sure, the adoption of contraception has been the principal source of fertility decline in LDCs. However, it is more difficult to see why and how couples adopt contraceptive practices. It is a function of many influences, not only to do with the presence in a country of a family planning program. The synergism between the various factors national family planning programs combined with socioeconomic development and empowerment of women result in fertility decline. However, there is one indication that may be the key to the lowering of fertility levels in LDCs: female basic education. It is of importance to the three synergetic factors mentioned above (*see* Ecofeminism, Volume 5).

Female education has long been known as the strongest social correlate of fertility, far stronger, for instance, than income, occupation, labor-force participation, and the like (Cochrane, 1979; Cleland and Wilson, 1987; Cleland and Rodriguez, 1988). Even when controlling for socio-economic status, the independent effect of education exceeds that of any other factor (United Nations, 1987, 1993). One part of this impact is an accounting effect: if girls attend secondary school, age at first marriage, one of the principal proximate determinants of fertility, is higher. More important, however, is the effect of education on values and tastes that provide the context for fertility decisions. The strongest intermediate link between female educational attainment and lower fertility is the greater likelihood that married women who were schooled as girls will use contraception. While there are increasing returns (in terms of lowered fertility) as the number of years of schooling rises, women who have had even a few years of primary schooling are observed to be more likely to practice contraception than those who have had none.

Part of the effect of girls education is economic. It increases the cost of children by making girls unavailable

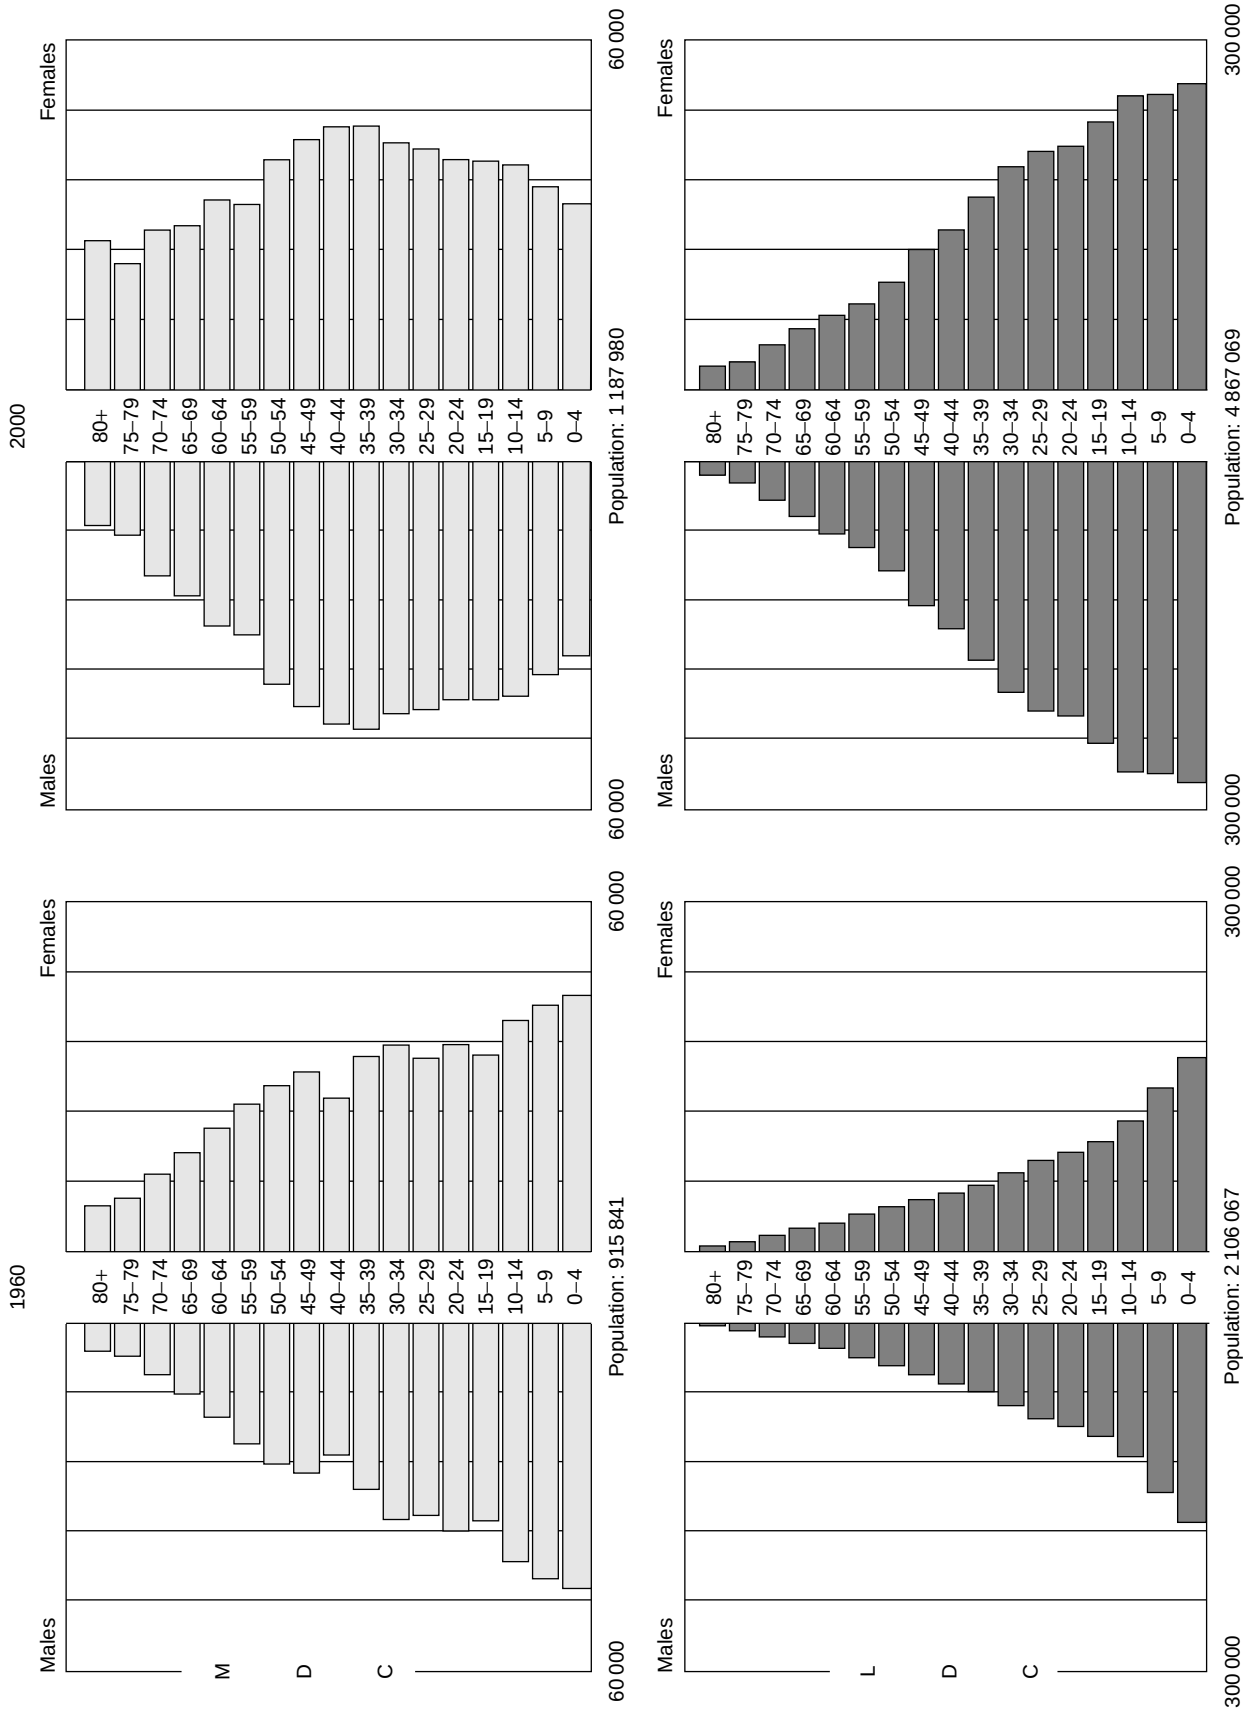

Figure 1 Population pyramids for MDC and LDC in 1960 and 2000

for domestic chores; educated mothers are also more likely to earn income outside the home than uneducated ones, and hence face higher opportunity costs in child rearing. But there is more to education of girls than just shifting economic costs and benefits. Parents decision to endow girls with even a modicum of education, as opposed to none at all, reflects a fundamental shift in the status of women. It sets in motion an irreversible shift in women s perceptions, ideals, and aspirations (Cleland and Wilson, 1987; Kasarda *et al.*, 1986). Women who have been educated are better able to follow their own, usually lower, fertility desires rather than those of their husband or their extended family. Another possible link between women s status and low fertility might be through improved health of children. Closely related to the low status of women are poverty and insecurity, both of which raise the value of children as economic assets (in particular, as sources of old-age security) and impede the attitudinal change necessary for fertility decline (Thomas, 1991). Finally, provision of basic female education promotes a political culture and civil society in which national family planning programs are likely to be established and function effectively.

POPULATION PROJECTIONS

The most-used method for population projections is the so-called *cohort-component model*, which projects the population by age group. This method was introduced by Whelpton in 1936, formalized by Leslie in 1945, and first used to project the world population by Notestein of the same year. The cohort-component method recognizes the strong effects of age structure on population dynamics and growth. *Cohorts* are groups of men and women born during the same time interval and representing a specific age group at any later point in time. Cohort size can only change through mortality and through migration. The size of the youngest age group is determined by age-specific fertility rates applied to the corresponding female cohorts of childbearing age. Hence, the projected size and age structure of the population at any point in the future depends exclusively on the size and age structure in the starting year, combined with assumed age-specific fertility, mortality, and migration rates over the projection period. These three variables determine all future population trends.

Population growth is also characterized by a momentum that arises from the persistence of a population s age structure. The youthful age structure of a high fertility population ensures that it will continue to grow for many years, even if the TFR declines rapidly, since for a generation progressively larger cohorts of young women will be entering their reproductive years. Population momentum has two important implications. First, population size reacts only very slowly to shifts in fertility parameters. For example, if LDC fertility rates were suddenly to decline to replacement levels, population in these countries would still continue to grow for several decades before leveling off. Second, this population inertia allows demographers to project population several decades into the future with a fair degree of confidence, just because the population that will be alive 25 years from now has already been born. Migration is the most volatile parameter since it depends in part on political conditions; fertility and mortality tend to change more slowly over time.

In this section, we summarize the assumptions and results of the population outlook published by IIASA (Lutz, 1996). These projections differ from others, such as United Nations (UN) projections, in three respects: (1) there is extensive discussion of the basis for assumed fertility, mortality, and migration trends; (2) alternative paths of future mortality and migration, in addition to fertility, are incorporated into the projections; and (3) probabilities are attached to alternative population paths.

Methodology

It has become the standard practice of most national and international agencies that prepare population projections to provide the user with a medium variant resulting from a set of assumptions considered most likely, plus low and high variants based on different assumptions and resulting in lower and higher total population sizes, respectively. Although such low and high variants are sometimes misunderstood as providing confidence intervals in a probabilistic sense, they typically are not based on any systematic variation of parameters, but simply represent alternative sets of fertility assumptions. That is the case for example of projections prepared by the UN Population Division (UN, 1998).

IIASA invited a number of experts on fertility, mortality, and migration to write chapters that summarized the existing demographic knowledge relevant for specifying the uncertainty range of future trends. These experts were asked to provide, for 13 world regions in the period 2030 2035, high and low estimates, designed to cover approximately 90% of the possible range, for fertility, mortality, and migration parameters. Central variant assumptions were taken as averages of the high low range. Assumptions for 2030 2035 were extended to 2080 2085 as described below and were held constant thereafter, until 2100.

The Future of Fertility

The level of fertility has in the long run the greatest impact on population growth. Its power derives from the multiplier effect of each additional child born today having additional children in the future.

In Developing Countries

Assumptions about future fertility for each of the world regions must consider present and past fertility. However, birth registration systems are very weak in most developing countries. The most reliable source of fertility related data are the international surveys conducted since the 1970s most important among them the World Fertility Surveys and the Demographic and Health Surveys. Table 2 gives an example of measured TFRs in some developing countries, with estimated desired fertility and the percentage of women using a contraception method modern or traditional during the last 10 years. The table shows that many women have more children than they want, even in countries where contraceptive prevalence is relatively high, e.g., in the Latin American and Caribbean region. Sub-Saharan Africa has by far the highest fertility levels (effective and desired) and the lowest levels of contraceptive prevalence. Within this region, countries with the

lowest use of contraceptive methods such as Niger, Mali, and Burkina Faso have the highest fertility rates. However, in all African countries, the desired TFR of women interviewed during the survey are clearly lower than the actual rates. The difference is two children in Kenya and Rwanda, and more than one in Benin, Comoros, Ghana, Uganda, and Zambia. This, together with indications of increasing contraceptive prevalence, leads to the expectation of significant fertility declines in the next decade even in sub-Saharan Africa, where fertility has remained persistently high until recently.

In North Africa, the fertility transition is already much further advanced, and half of the female population employs contraception, considerably more than in the rest of Africa. From the two countries chosen for the Middle East, Jordan shows a relatively high contraceptive prevalence more than one-third of the female population and a desired fertility of 3.9. The second country Yemen has very low current use of contraceptive method as well as very high desired fertility although the difference is almost two children. Further declines are also to be expected in this region unless dramatic events, such as a rise in pronatalist traditional religious values, change the pattern.

Three of the five Asian countries considered here, Bangladesh, India and Indonesia have TFRs between 2.9 and 3.4. The TFRs of Nepal and Philippines were still above four children but in all those countries the desired fertility was below three children, pointing to some further decline in the region.

Contraceptive prevalence is high in many Latin American countries more than 60% in Peru and the Dominican Republic and Colombia, and almost 80% in Brazil. In terms of desired and actual fertility, Latin America has an intermediate position, comparable with that of North Africa. Further fertility declines can be expected in that region.

For the longer-term future, general social and economic development, together with cultural and political factors, will determine the course of fertility decline. Although our understanding of the causal mechanism at work is incomplete, the evidence favors further fertility decline in LDCs. Therefore, even high fertility variants in these regions generally call for fertility to be lower in the period 2030 2035 than it is today. One exception is China, where the high variant assumes that the country s one-child policy is relaxed to allow fertility more in line with desired fertility levels. High-variant fertility assumptions for other regions are that the ongoing fertility transition is retarded or stalled. That this can easily occur is illustrated by the important case of India, where fertility decline was arrested between the late 1970s and the early 1990s at a TFR of about four.

Relying on the concept of *demographic transition*, population forecasters have conventionally assumed that every country will reach replacement level fertility sometime in the future, even for European populations that have already been far below that level for extended periods, implying increases in future fertility for these countries (*see* Demographic transition, Volume 5). This replacement level assumption is mechanistic, however, and is usually not supported by much substantive analysis. Therefore, our low-variant assumptions imply that fertility decline in LDCs, as in MDCs, does not stop at a TFR of 2.1, but continues to decline, carrying countries into the

Table 3 Alternative fertility, mortality, and migration assumptions for world regions in 2030–2035

range of sub-replacement fertility. The central assumptions, which represent the most likely case, result in fertility slightly above replacement level in 2030 2035 in most LDC regions substantially so in sub-Saharan Africa (see Table 3 on assumptions).

Fertility assumptions were extended into the future by assuming that in 2080 2085, the TFR in all LDC regions will lie between 1.7 and 2.1, depending on the population density of the region. Although there is some empirical evidence that high population density tends to induce lower fertility after controlling for other factors (Lutz, 1997), this procedure is still somewhat *ad hoc*, although no more so than the common alternative, which is to assume that fertility falls (or rises, as the case may be) to replacement level and then remains fixed.

In MDCs

Making assumptions about future fertility in populations that have already passed the demographic transition is easier than for today s high fertility because the range of possible fertility rates is narrower, i.e., for a modern urban society with high female labor-force participation, it is unlikely that fertility will be significantly above replacement level. It is harder because the direction of change i.e., whether fertility will increase or decrease is unclear. It seems unlikely that fertility will remain permanently below a level that is only around half the replacement level. On an individual level, the desire for children is deeply rooted, and on a societal level, extreme population aging would bring serious problems that, in turn, might lead to measures aimed at increasing fertility.

Figure 2 plots the trends in TFRs for selected European countries since 1950. It shows the baby boom during the 1960s, which was a phenomenon common to all Western industrialized societies. The increase in births was mostly due to economic prosperity that caused a marriage boom, as well as an increase of fertility within marriage. The 1970s were characterized by rapid fertility declines in almost all countries, beginning with the northern and western European countries. The southern European countries lagged somewhat behind, but subsequently experienced an even steeper decline. Greece, Italy and Spain are currently experiencing the lowest fertility levels in Europe, with TFRs as low as 1.2 children per woman. In France, and especially in Scandinavia, fertility has never declined to such low levels. In Sweden, fertility showed a temporary increase to replacement level during the 1980s. This increase seems to have been associated with generous family benefits and excellent

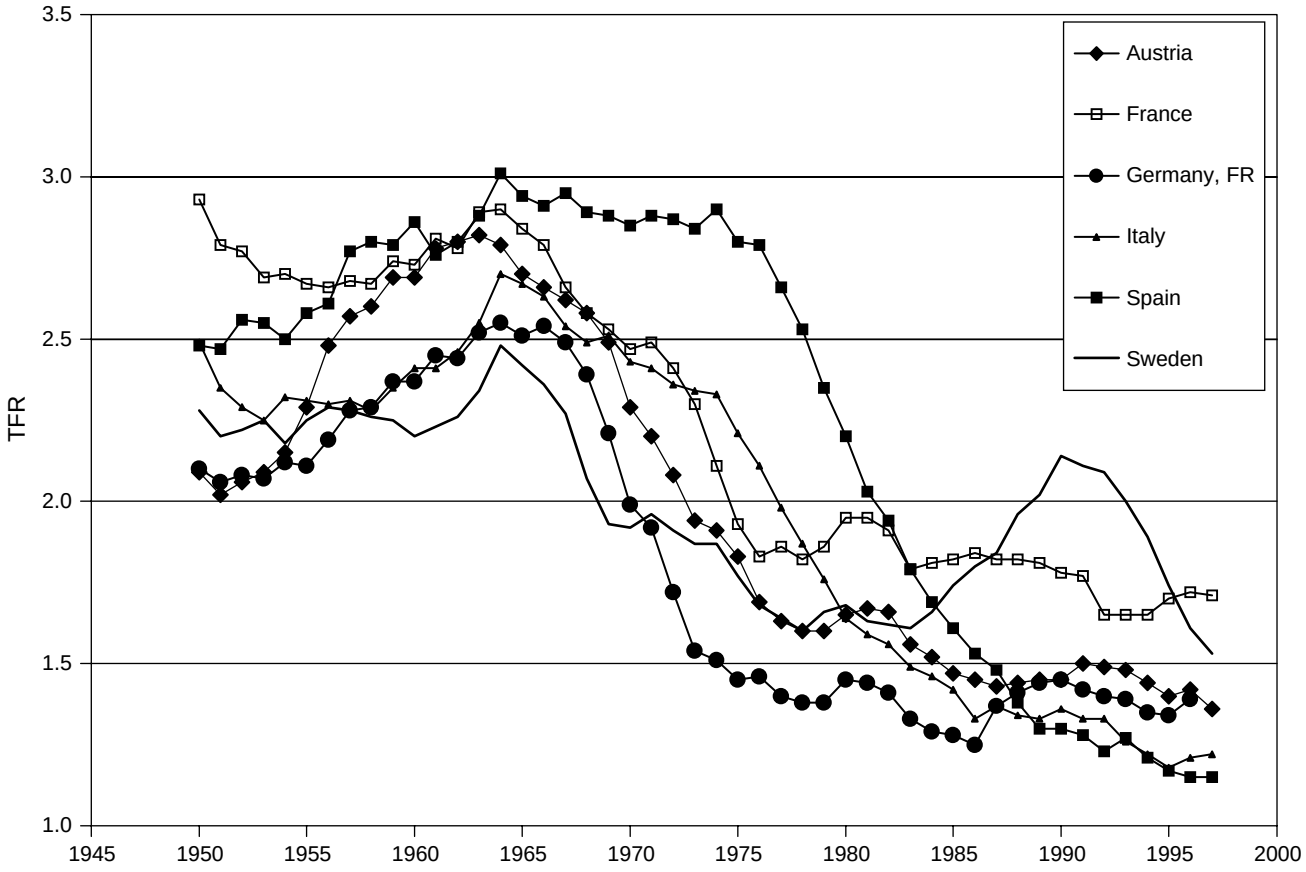

Figure 2 TFRs in selected European countries, 1950–1998

childcare provisions that facilitated the combination of child rearing and work outside the home. In the first half of the 1990s, however, fertility in Sweden came down again.

As the historical record in the developed world is mixed, the direction of future fertility trends is not clear. For their high variant, the IIASA projections assume a return-to-replacement level fertility (or slightly above) by 2030 2035 (see Table 3). The assumptions are slightly higher than replacement fertility levels for North America because of the different ethnic composition. This assumption, common to the central variants of other institutions discussed above, is theoretically supported by the homeostasis argument, which says that individual behavior is a function of the system. Therefore, fertility levels are not so much the sum of individual behavior, as one aspect of the evolution of a system where individual behavior is a function of the status of the system (see Vishnevsky, 1991). Under such a systems approach, the assumption of replacement fertility in the longer run makes sense.

There has been criticism of the homeostatic systems as too much evidence points toward continuing low fertility in industrial countries. The return to replacement fertility has been criticized as an assumed magnetic force (Westoff, 1991) without empirical support, while there are many significant arguments supporting an assumption of further declining fertility levels. These include the weakening of family ties both in terms of declining marriage rates and high divorce rates, the increasing independence and labor-market orientation of women, and the value change toward materialism and consumerism. These forces, together with increasing demands and norms concerning the resources (personal attention, education, money, etc.) to be given to children, is likely to result in fewer couples with more than one or two children, and an increasing number of childless couples.

A further argument suggesting lower fertility is that surveys still show very high proportions of unplanned births, even in societies where contraception is universally available. For example, in Canada, Japan and the US, about 30% of births are estimated to be unintended at the time of conception (Brown and Eisenberg, 1995; Montgomery, 1996; Henshaw, 1998; Alan Guttmacher Institute, 1999). A third of these are unwanted (born to women who did not want any more children) and the rest are mistimed (born to women who did not want to become pregnant until a later time). If contraceptive methods without side effects were developed that required positive action in order to become pregnant instead of forethought to avoid pregnancy, the number of births would most likely decline further.

The bulk of evidence therefore suggests that fertility will stay low or even further decline in industrial countries. How far it can decline is not clear. Golini (1998) recently suggested an absolute lower limit of about 0.7 to 0.8 children per woman based on the assumption that 20 30% of women remain childless and the rest have just one child. The IIASA projections set low values (which assume only a 5% probability of even lower levels) by 2030 2035 of 1.4 in North America and 1.3 in the other developed regions, with central variants obtained by averaging high and low assumptions.

The Future of Mortality

More so than for fertility, changes in the level of mortality are directly related to biomedical aspects of development. They also reflect changes in behavior, through the choice of individual lifestyle (such as smoking), which, at least in low mortality countries, has a significant impact on individual survival probabilities.

The uncertainties about future life expectancies are quite different in today s high and low mortality countries. Both have seen impressive increases in life expectancies. It is no longer uncommon for individuals in MDCs to survive to ages that used to be considered a biological upper limit to the human life span. Assumptions about future improvements depend on whether or not such a limit exists and will soon be reached. In regions that still have much lower life expectancy, this question is irrelevant and future mortality conditions will be determined by the effectiveness of local health services, the spread of both traditional (e.g., malaria) and new diseases (e.g., AIDS), and the general standards of living and education. Given even modest social and economic development, and apart from the AIDS epidemic, it is likely that the gap between life expectancy in MDCs and LDCs will narrow further.

In Developing Countries

Generally, most of developing countries show almost linear improvement of their life expectancies over the past 40 years, with several gaining more than 20 years of life expectancy. Probably the most impressive increase (about 25 years) occurred in China. India also had a very substantial increase from less than 40 years in 1955 to around 60 years in 1995 (Figure 3).

As with fertility, uncertainties about future mortality trends are highest for sub-Saharan Africa, partly due to the lack of reliable data. For example, the stalling of infant and child mortality declines in some countries could be due to poor data quality (Bucht, 1996). There is no doubt that modern health infrastructure developed significantly after 1960, as shown by an increasing number of health personnel *per capita*. Efforts were also made to introduce new vaccines and to build up primary health care strategies throughout the continent. Garenne (1996) concludes a survey of African mortality by stating that if in the past, transfers of technology from the West made most of the difference, then in the

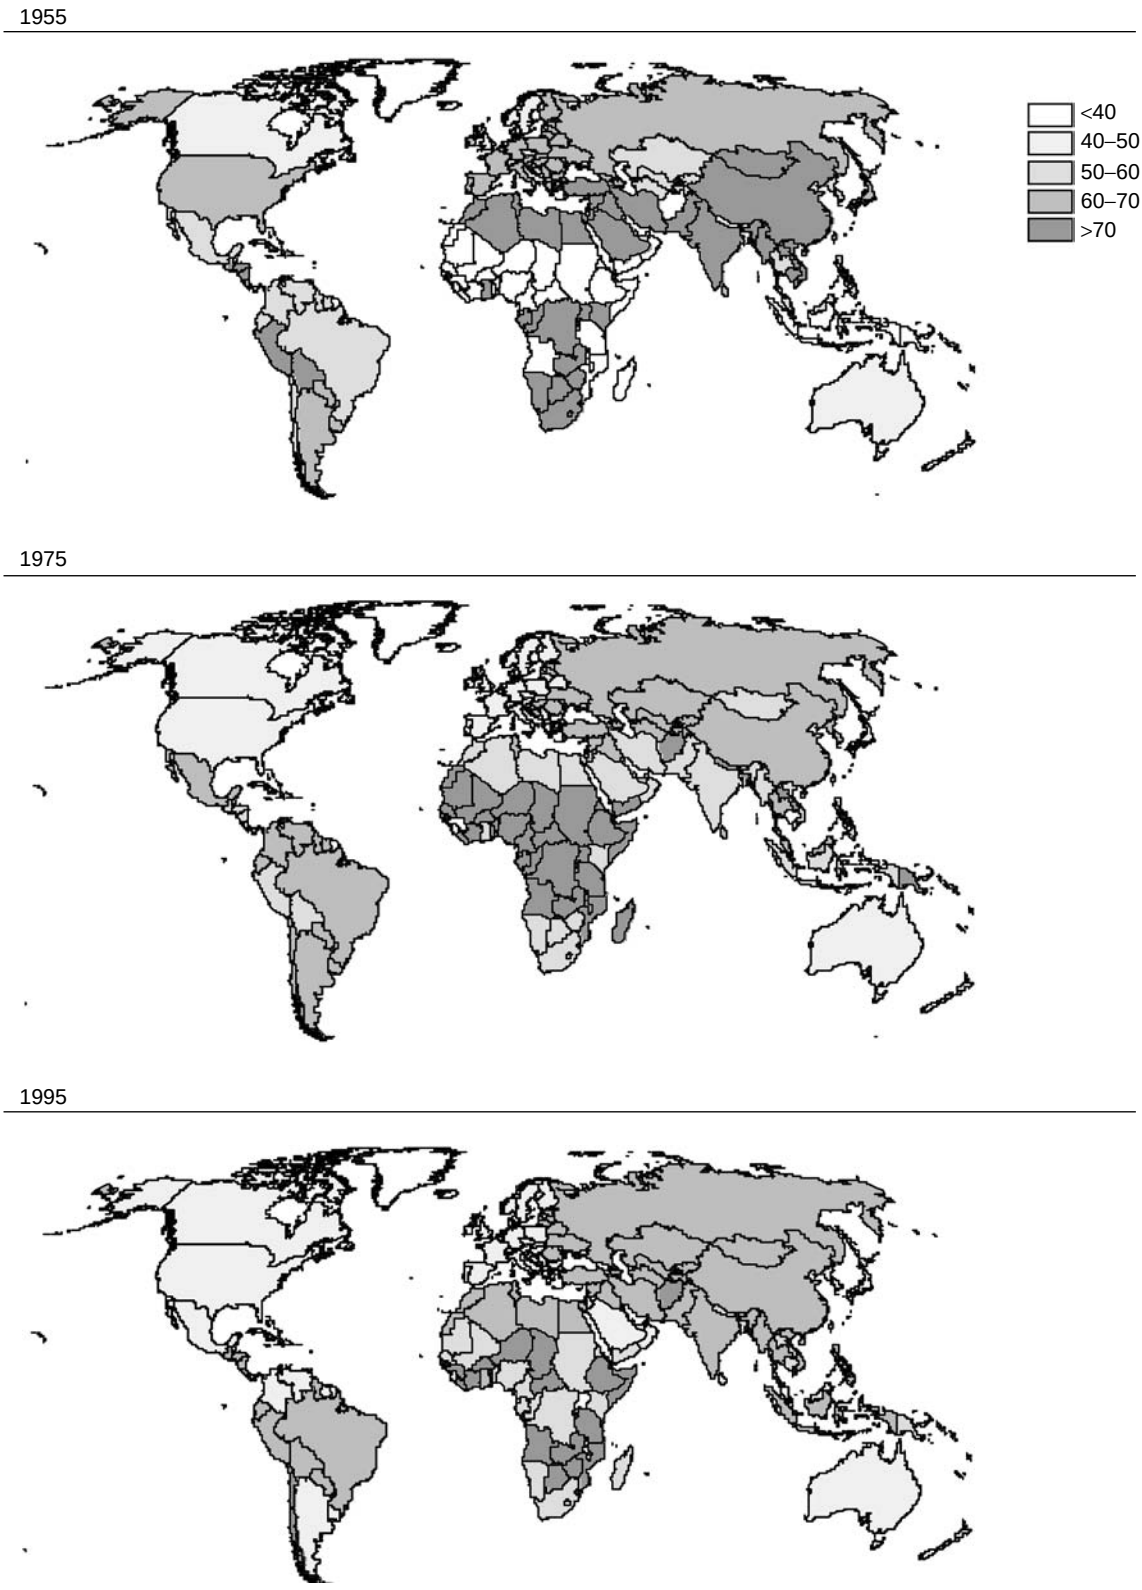

Figure 3 Life expectancy at birth in years in the calendar years

future, public health, nutrition, economic development, and education will be the key determinants of mortality decline. The spread of infectious diseases, especially HIV, as well as problems of basic subsistence, may arrest the declining trend of mortality of the past 30 years.

The sheer number of deaths due to AIDS in Africa, and hence the magnitude of the epidemic on a human and social scale, is immense. By subjecting members of the most economically active and productive groups to a wasting and premature death, AIDS is imposing an enormous economic and social toll on the continent (Ainsworth and Over, 1994). The ultimate impact of AIDS on the population of Africa as a whole will be moderate if, as assumed by Bongaarts (1996) and others, exceptionally high HIV prevalence rates exist only in a few countries, e.g., Botswana and Malawi. If high prevalence rates turn out to be more widespread, AIDS could have a significant impact on African population dynamics. Recent simulations for Botswana (International Institute for Applied Systems Analysis, 2001), which has an HIV prevalence rate estimated to be well above 30% among pregnant women, indicate that total population size may well decline or stabilize due to AIDS. Moreover, the age structure will become severely distorted and rural populations will become more vulnerable with increasing proportions of AIDS orphans and elderly. The macro economic consequences of rising health expenditures, and a worsening health status of the labor force will differ markedly depending on the economic structures of different countries.

In terms of the scenario assumptions, for sub-Saharan Africa the IIASA projections assume a two-year per decade decline in life expectancy as the low value, and a three-year increase as the high value, resulting in a one-year increase per decade for the central scenario. AIDS is also taken into consideration in the mortality assumptions for southern Asia and Southeast Asia, where the low case assumes zero improvements in mortality. The high values assume that AIDS can be largely brought under control and mortality will improve quickly following the path of today s industrialized countries.

In MDCs

Currently, Japan holds the highest life expectancy of any major country: 82 years for women and 77 years for men. Only three decades before, in 1960 1965, life expectancy was 72 for women and 67 for men, implying an average increase of more than three years per decade for Japanese women and men. Eastern Europe, on the other hand, had life expectancies similar to those of Japan during the early 1960s but has had little improvement (or even declines) since then, bringing life expectancy to about 74 for women and 63 for men at present. Western Europe and North America take an intermediate position, with life expectancies that have increased steadily by about two to three years per decade. The recent trend points toward further increases but, with indications of an imminent leveling off (Valkonen, 1991). For example, studies on occupational mortality differentials in the Nordic countries which are more homogeneous than many other countries still show significant inequalities, mostly by social class (Andersen, 1991), which may be taken as an indication of the possibility of further improvements if the higher mortality groups change their lifestyles.

The existence of a fixed biological limit to the human life span is controversial. The more traditional view implies lower rates of increase in life expectancy in the future. According to its defenders, aging is a process intrinsic to all cells of the human body. Recent and possible future mortality improvements are interpreted as a rectangularization of the survival curve through the elimination of premature deaths and resulting concentration of mortality shortly before the maximum age (Duchene and Wunsch, 1991). Lower rates may also be induced by worsening living conditions, health-impairing behaviors, or worsening environmental pollution (Day, 1991). Olshansky *et al.* (1990) also argue that an increase in life expectancy beyond 85 is unlikely because it would require a decline of more than 55% in mortality rates from all causes at all ages, which is improbable. Following these lines of reasoning, the IIASA scenarios assume an increase in life expectancy of only one year per decade (for both men and women) as the low value.

The alternative view sees that under favorable conditions, we could see much higher levels of life expectancies in the future. Aging is seen as a multidimensional process of interaction, in which partial loss of function in one organ can be compensated by other organs, and only total loss of a necessary organ system results in death (Manton, 1991). Manton *et al.* (1991) present impressive evidence from small special populations followed for short periods of time that show average life expectancies of well above 90 years. Further supporting evidence for this can be found by studying changes in very old age mortality over time. Using Swedish data since 1900, Vaupel and Lundstom (1996) show that mortality rates at ages 85, 90, and 95 have substantially declined at an accelerating rate, which over the past decades averaged 1 2% year$^{\bullet 1}$ for women and 0.5% for men. These considerations provided the motivation for the assumption of much more signi cant increases in life expectancy in the IIASA high scenario three years per decade than those assumed by most other national and international population projections. The average of the high and low scenarios results in a central scenario increase in life expectancies of two years per decade.

Assumptions on Future International Migration

International migration is the most dif cult component of population change to project. Short-term political and

economic changes in both the receiving and sending countries can affect migration trends. Net migration always results from the combination of two partly independent migration streams: that entering and that leaving a certain region for whatever reasons. Furthermore, the reliability of statistical data to assess past and present legal and illegal migration levels is meager, and more importantly, migration streams are volatile. For example, during the early 1970s, West Germany had an annual net migration gain of more than 300 000; this had declined to only around 6000 five years later, and even to 3000 during the early 1980s. During the 1985 1990 period, however, the annual net gain increased sharply again to 378 000, 100 times that of the previous period. These ups and downs exist also in the traditional countries of immigration the US, Canada, and Australia. Annual net migration to Australia declined from 112 000 in the early 1970s to 54 000 in the late 1970s. During the 1980s, it increased again to over 100 000. In this sense, labor immigration within Asia has been remarkable over the past decades. For instance, during the late 1980s more than 430 000 workers left the Philippines annually, with around 280 000 of them going to the Middle East. The Republic of Korea lost an average of 170 000 workers each year during the early 1980s; India lost 240 000 and Pakistan 130 000 annually during the same period. The largest proportion of these workers went to oil-rich countries in the Middle East. During the late 1980s these migratory streams within Asia showed significant declines.

There is potential for further increases in interregional migration due to better communications between regions, cheap mass transport, and the persisting gap between the North, which is not only richer but also rapidly aging and in need of young labor, and the South, which has many young people with rising skill levels but low income opportunities in their home countries. In addition to these economic factors, expected environmental changes in many parts of the world may cause further significant pressure to migrate to other regions where conditions are perceived to be better.

Still, the actual extent of future South North migration streams depends not only on pull and push factors, but also on the immigration policies of the receiving countries. If the European Community, for instance, were to enforce a policy of closed outside borders, this might result in a situation of almost no net migration. Hence for all regions, the low scenario value for net migration chosen was zero. This is not the same as assuming that borders will be closed to migrants; it only implies that, on average, the number of in-migrants approximately equals the number of out-migrants.

For the high migration scenarios, annual net migration gains of 2 million in North America, 1 million in Western Europe, and 350 000 in Japan/Australia/New Zealand have been assumed. For Eastern Europe special assumptions were made for the period 1990 2030, with out-migration dominating the first decade.

The distribution of migrants from the assumed sending regions to the receiving regions, and migration patterns among the developing regions, are based mostly on currently observed migratory streams as given in Zlotnik (1996). Annual net migration is assumed to be • 475 000 in northern Africa, • 510 000 in sub-Saharan Africa, • 650 000 in Central America, • 260 000 in South America, • 15 000 in western Asia, • 835 000 in Southern Asia, • 470 000 in China, and • 1 135 000 in Southeast Asia (see Table 4). Model migration schedules by Rogers and Castro (1981) were used to determine the age patterns of migrants.

The IIASA 1996 Population Projections: Results

Using the high, central, and low scenarios for fertility, mortality, and migration in 13 world regions, a number of projections of future population were performed

Table 4 Assumed central values of annual migration flows in thousands

over the 1995 2100 period. We summarize results of two distinct approaches. More detailed results can be found in Lutz (1996). A complete set of results is available from the authors and accessible on the IIASA Web site at the address show below; in this set the results are arranged by five-year age groups in five-year time intervals (1995 2100) for all 13 regions and 27 scenarios. See: http://www.iiasa.ac.at/Research/POP/docs/Population_Projections_Results.html. In the first approach, the systematic combinations of the three values (low, central, and high) for all three demographic components (fertility, mortality, and migration) result in 27 scenarios for future population and age structure. A comparison of these scenarios allows conclusions to be drawn regarding the sensitivity of results to the underlying assumptions. In the second approach, the high low range for each vital rate is interpreted as a 90% uncertainty interval and a set of probabilistic projections is performed, resulting in a distribution of outcomes for population size and age that provides new insight into the likelihood of demographic trends over the next 100 years.

Table 5 shows the total population size in 1995, 2020, 2050, and 2100 for the nine scenarios resulting from the combination of the three fertility assumptions (low, central, and high) with the three mortality assumptions. Migration is held at its central level in all of these scenarios. Results are presented at the level of major world regions. The central scenario (combination of central fertility with central mortality assumptions) describes the most likely future population path under our assumptions. If these central assumptions hold for all world regions, then the total world population will increase from 6.0 billion in 2000 to 7.9 billion in 2020, 9.9 billion in 2050. This scenario implies a clear leveling off of world population growth toward the end of the 21st century. The world population reaches an all-time high of 10.6 billion around 2080, and starts to decline somewhat to 10.4 billion by the end of the 21st century (see Figure 4).

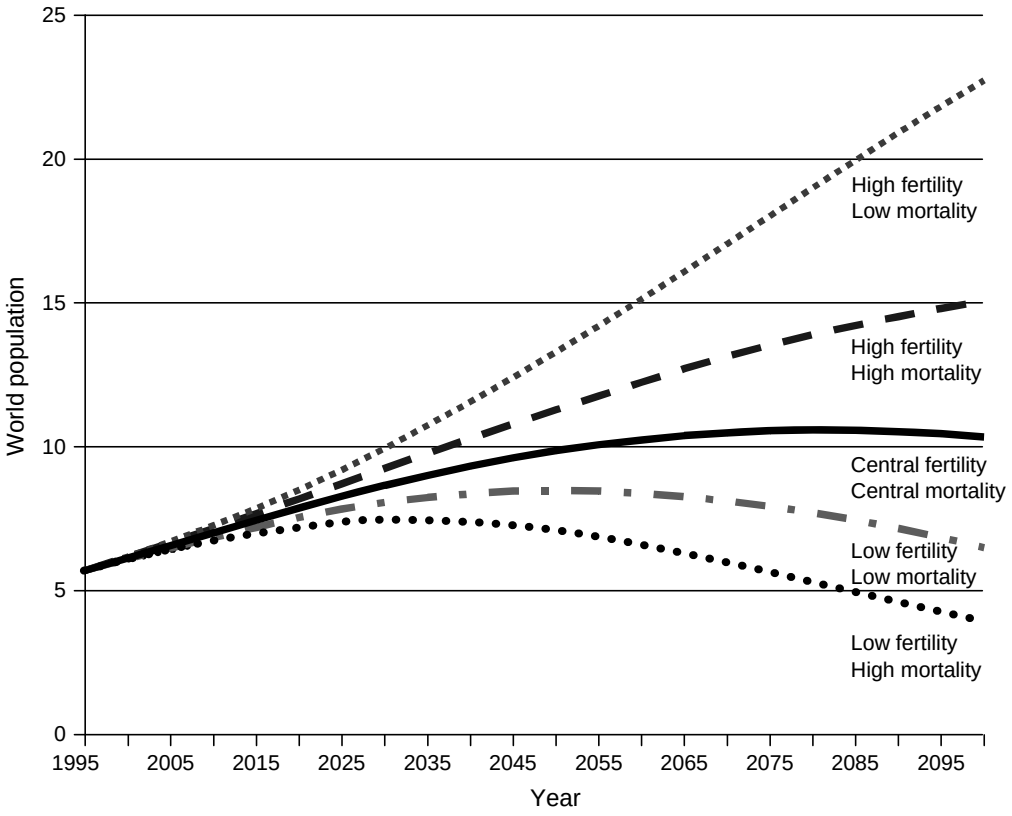

Figure 4 Selected projected paths of world population size (five scenarios, central migration)

The highest population path combines low mortality with high fertility, producing a world population of 13.3 billion by 2050 and 22.7 billion by 2100. The lowest population path results from combining high mortality with low fertility in every world region. In this case, world population levels off during the 2030s, reaches 7.1 billion in 2050, and by 2100 declines to about 4 billion. However, these extremes are considered unlikely. If fertility remains high in LDCs, it is likely to be a result of slow economic and social progress, in which case it is more likely that mortality will be high, not low. Similarly, if rapid change results in low fertility, it is more likely that mortality will be low, not high.

Scenarios corresponding to more plausible combinations of assumptions might be called the rapid demographic transition scenario (low mortality and low fertility) and slow demographic transition scenario (high mortality and high fertility). These less extreme (from the standpoint of population growth) but more meaningful scenarios are given in the upper right and lower left corners of Table 5. In the first case, world population rises to 15.1 billion in 2100; in the second case, it rises to 8.5 billion in 2050 before declining slowly to 6.5 billion in 2100.

These global totals hold only if fertility and mortality trends are perfectly correlated across all world regions (for example, all regions simultaneously follow the high fertility assumptions). In the real world, however, it is much more likely that one region will follow one scenario while another follows an alternative scenario. Why, for example, should the fertility trend in Latin America be correlated to that in Eastern Europe? Table 4 allows the user to define any mix of scenarios in different world regions and aggregate them into global population sizes. All these regionally mixed scenarios will lie between the extremes because diverging trends in different regions will partly offset each other.

The global world population growth results from a great diversity of regional patterns. Under the central scenario, the population on the African continent would grow the most rapidly, almost tripling over the next five decades. Accordingly, the share of the world population that lives in Africa increases from 13% in 1995 to 21% in 2050. The population of East Asia increases by 41% under the central assumption until 2050; it doubles in west Asia during the same period. Latin America currently has 8% of the world s population; it is likely to maintain this proportion because its growth is expected to be close to that of the world average. The proportion of the world population living in Europe falls from the current 14% to 7 8% by 2050. Europe and North America both grow below the world average under all scenarios.

Table 6, which gives results for population aging, here indicated by the proportion of the population above age 60, shows that significant population aging is inevitable. Universal population aging is the most consistent and dominant population trend of this century. Even in the slow demographic transition scenario combining high fertility with high mortality (which also tends to reduce aging), the proportion above age 60 increases from the current 9.5% to 17.8%. In the rapid demographic transition scenario combining low fertility with low mortality, the proportion above age 60 increases to 42.5% of the total population. Considered in terms of increases in absolute size of the population above age 60, rather than as increases in the proportion, the rapid and slow demographic transition scenarios, as well as the central scenario, imply a fivefold increase in the 60• age group in the long run. Among the developing regions, China together with its centrally planned economy, is certain to experience the most rapid aging because fertility has already declined dramatically. Within less than four decades China s old age dependency burden will be higher than North America s today.

In MDCs, although the proportion of elderly is already quite high, further and signi cant increases are inevitable. For example, in North America, the population over 60 years of age represented about 16% of the total population in 1995. As a result of the large cohort born during the post-World War II baby boom, the share of the population below age 60 will still increase in the next decade. However, when the baby boomers reach age 60, after 2010, the proportion of elderly will soar, reaching between 23 and 34% by 2030, depending on the fertility, mortality and migration assumptions. The central most likely scenario projects that 28% from North America will be 60 years of age or older by 2030.

Deceleration of population growth is a broadly supported goal of international population policy. The estimates in Tables 5 and 6 reveal, however, two quali cations that should be kept in mind. First, the faster that fertility

declines, the faster that mortality is likely to decline as well, the more population aging is accelerated and intensified. Second, low population growth may be desirable but is associated with the highest mortality, which is hardly a desirable option. On both counts, population stabilization is not a goal that should be pursued blindly.

Fertility assumptions, as was mentioned at the beginning of this section, have a far greater impact on projected long-term population size than do mortality assumptions. Holding fertility and international migration assumptions at their central values and allowing only mortality assumptions to vary, the forecast range for 2100 is between a population of 8.1 billion in the high mortality case and 12.7 billion in the low mortality case. Holding international migration and, this time, mortality assumptions at central values and allowing only fertility to vary, the range of variation is between 5.1 billion in the low fertility scenario and 19.0 billion in the high fertility scenario.

Considered region by region, population size is more sensitive to the future course of fertility in LDCs than in MDCs, where the range of possible variation in behavior is lower and the base is smaller. Fertility trends are the dominant influence on population size, but sensitivity to mortality trends is significant enough to justify alternative mortality assumptions. Fertility is also the most important factor governing population aging. Under central mortality and migration assumptions, the high fertility scenario implies 19.9% of the population over age 60 in the year 2100 and the low fertility scenario implies 37.2% a spread of over 17 percentage points (see Table 6). Under central fertility and migration assumptions, however, the high mortality scenario implies 24% of the population over age 60 and the low mortality scenario implies 30.8%, a spread of only about seven percentage points. Migration assumptions have even less impact on aging than mortality. Taking Western Europe as an example, if mortality and fertility assumptions are held at central levels and migration assumptions are varied, the forecast range for the proportion of the population over age 60 in 2100 is only between 34.1% in the high migration case and 36.5% in the low migration case. In terms of absolute change in the proportion of the population over age 60, both regions are about equally sensitive to the future course of fertility. For example, in 2050 the difference between the low and central fertility scenarios (given central mortality and migration assumptions) is 6.5 percentage points (40.2% as opposed to 33.7%) for MDCs and 4.8 percentage points (22.2% as opposed to 17.4%) for LDCs.

Probabilistic Projections

All the scenarios described above represent more or less combinations of assumptions, which have no probabilistic interpretation. There is no one simple way to apply probabilistic methods to population projections (see Lutz *et al.*, 1999; Lee, 1999). The IIASA projections use an approach that is based on expert judgment. The procedure fits a normal distribution to the three values (high, central, and low) that resulted from the expert discussions, with 90% of the cases lying between the high and low values. Sensitivity analysis showed that the results are relatively insensitive to the chosen value for the confidence intervals. Thus, the high low range may be thought to cover 85 95% of all cases (see Lutz, 1996). Results were derived through a set of 4000 simulations that randomly combined fertility, mortality, and migration paths from the three normal distributions for the 13 world regions. These simulations also considered the possibility that fertility and mortality trends may be correlated within regions (e.g., high fertility in sub-Saharan Africa is more likely to go hand in hand with high mortality than low mortality) and that regional trends may be either independent of each other (e.g., fertility in sub-Saharan Africa uncorrelated with fertility in Latin America) or correlated.

Figure 5 shows the distribution of future population sizes derived from the full set of 4000 projections at five-year intervals to the year 2100. The high and low boundaries give the range into which 95% of all cases fall. The upper line indicates that there is an unlikely possibility of almost linear population growth between 1995 and 2100. The lower line shows that there is also an equally unlikely possibility that the world s population will peak in the middle of the 21st century and fall thereafter to below 6 billion by 2100. The much more probable range of future paths (between the 0.2 and 0.8 fractiles, covering 60% of all cases) is remarkably small. By 2050, this uncertainty range is less than 1.5 billion people, and by 2100 it doubles to about 3 billion people. The figure also shows that in more than 60% of all cases, total world population levels

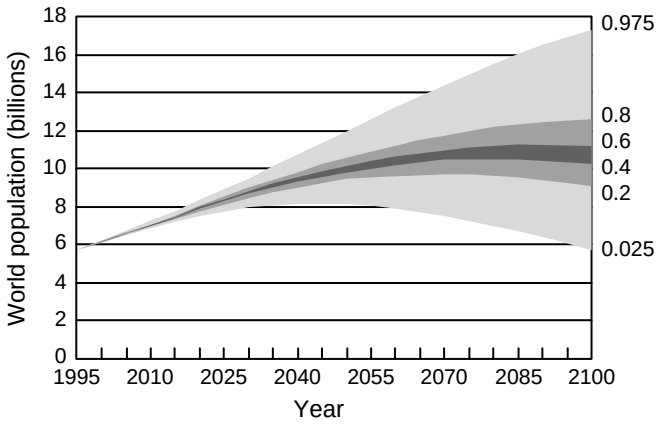

Figure 5 Merged distribution of the size of the world's population (in billions), 1995–2100. The figures on the right-hand side show the proportion of cases in which the percentages falls below the line indicated

off during the second half of this century, or even starts to decline. Given that the world population in mid-1996 was estimated at 5.8 billion, Lutz *et al.* (1996b, 1997) find that the probability of a doubling that is, reaching or surpassing the 11.6 billion mark at any point during the next century is only 33%. In other words, there is a two-thirds probability that world population will not double by the end of the 21st century.

When looking at regional disparities, Sub-Saharan Africa displays the largest range of uncertainty in future population size, with a 95% confidence interval in 2100 ranging between 578 million and 4.345 billion around a mean of 1.9 billion. This large range results from the unusually large uncertainty surrounding trends in fertility and mortality in the region, in addition to the assumption that the two trends will be uncorrelated. Lutz *et al.* (1996a) have shown that if fertility and mortality are instead assumed to be positively correlated within the region, the range of uncertainty becomes significantly smaller. The distribution of the percentage of the global population over age 60 is shown in Figure 6. All the lines are rising, indicating near certainty that the percentage of older people in the population will rise over time. In 2050, the median is 20% (with a 95% uncertainty interval between 15% and 26%), compared with 9.5% in 1995. By 2100, the median increases to 27%, with a 95% uncertainty range of 19% to 41%. In other words, there is a 95% chance that the proportion of the elderly will at least double over the next century. In the most likely case, it will almost triple and it may even more than quadruple. The uncertainty in the percentage above age 60 grows significantly during the second half of the 21st century, due mainly to the uncertainty in future old-age mortality when combined with uncertainty in fertility. To summarize, three near certainties emerge from the range of scenarios and

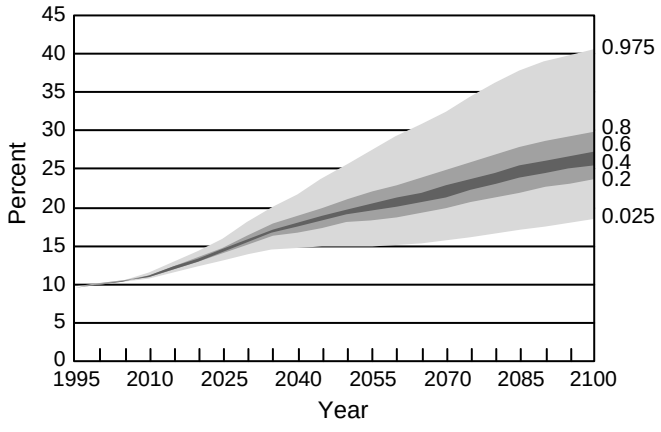

Figure 6 Merged distribution of the world's population in the 60• aged group (in percent), 1995–2100. The figures on the right-hand side show the proportion of cases in which the percentages fall below the line indicated

from the probabilistic projections. World population will increase substantially from its current level. Even in the lowest growth scenario, population increases by close to 2 billion before commencing its decline. However, a doubling of world population has become unlikely in the face of recent fertility declines. The distribution of world population will continue to shift toward LDCs. Even assuming rapid fertility decline and little improvement in mortality, LDCs still account for a rising share of world population. The world population will continue to age. Probabilistic projections show that a doubling of the proportion above age 60 is a near certainty.

CONCLUSION

This article has provided, through a wide range of extreme scenarios as well as a probabilistic population projection exercise, many possible numbers for the world population size for the next 100 years. In a nutshell, it has identified three near certainties in the world population outlook: further population growth, further tilt toward LDCs in the world distribution of population, and significant population aging. These robust findings embody the sectoral expertise of an international panel of researchers. They support the conventional wisdom that the speed of fertility decline in LDCs and, in the longer term, the ultimate fertility level reached there, are the key uncertainties from the standpoint of the future size and age structure of the total human population. Our understanding of the factors influencing fertility is far from complete. However, research supports the view that a combination of effective national family planning programs, socioeconomic development, and empowerment of women all with a special emphasis on education results in fertility decline.

Since it positively contributes to all three, investing in female basic education is likely the policy intervention that most strongly accelerates fertility decline. While less important than fertility, future mortality trends will also have a significant impact on future global population size and age structure.

It seems safe to predict, based on the projections summarized above, that the international population community, as well as policymakers, will gradually shift their concern away from population size and rate of growth to population age structure, specifically, aging. While the MDCs are entering unknown territory in terms of the proportion of the population over age 60, the LDCs are approaching the age structure of today s MDCs. Thus, under the central scenario, the proportion of the population over age 60 in MDCs is expected to rise from 17.7% in 1995 to 33.7% in 2050 while in LDCs it will rise from 7.2% to 17.4%. Based on the sensitivity analyses presented here, the extent of population aging is

equally sensitive to choice of fertility scenario in the two regions.

This expected new emphasis on population age structure, however, should not hide the fact that in some parts of Africa, Asia, and Latin America, populations are still expected to more than double over the coming decades, and many of these population live in fragile ecological systems.

Trends in Global Emissions: Carbon, Sulfur, and Nitrogen

ARNULF GRÜBLER

International Institute for Applied Systems Analysis (IIASA), Laxenburg, Austria

Global anthropogenic emissions of carbon, sulfur and nitrogen are reviewed by major category. Both present and historical emissions are reviewed including respective uncertainty ranges. The article concludes with a brief discussion of how to relate trends in emissions to the evolution of their underlying driving forces using energy-related carbon emissions as an example.

Main conclusions for the three gases are summarized below:

Anthropogenic emissions of carbon are small compared to the sizes of natural carbon reservoirs and the annual ow rates between them. Yet they constitute important perturbations of the natural carbon cycle, well quanti ed for industrial carbon emissions (mostly the burning of fossil fuels), but remaining uncertain for carbon emissions arising from biomass burning and land-use changes. Since the onset of the Industrial Revolution, some 530 billion tons of carbon (Pg C) gross emissions have been released by human activities to the atmosphere, part of which was balanced by (highly uncertain) terrestrial biospheric carbon sinks. Net carbon emissions over the period 1800- 2000 are estimated at 280 Pg C. After accounting for oceanic uptake, these emissions have increased the atmospheric carbon loading by 200 Pg C, or by one-third natural levels. In the absence of stringent climate policies, between 770 and 2540 Pg C could be released to the atmosphere over the next 100 years. A signi cant ampli cation of humankind's "discernible in uence on the climate system" is thus likely.

Anthropogenic emissions of sulfur have surpassed natural ows ever since the rst quarter of the 20th century. Since about 1975 global emissions (mostly from burning of sulfur-rich fossil fuels such as coal and oil) have stayed roughly constant. A continued rise in sulfur emissions in developing countries has been compensated by drastic declines in emissions in Organization for Economic Cooperation and Development (OECD) countries as a result of environmental policies. Similar policies will be required also in developing countries to counter local and regional environmental impacts of high sulfur emissions. A slowdown and ultimately a trend reversal of sulfur emission growth trends also in developing countries could thus be likely over the next few decades.

Emissions of nitrogen take a variety of forms and originate from a wide array of different sources including: nitrogen oxides, principally formed in high temperature combustion (burning of fossil fuels); ammonia, principally arising from animal manure; and nitrous oxide (N_2O), a powerful greenhouse gas, principally arising from soil microbiological process as well as agricultural activities and animal manure. Because of the multitude of gases and sources, emission estimates are poorly understood and uncertain. There is also a paucity of both past and present inventory data and future emission scenarios. More research is therefore needed before considering policy interventions to control these gases beyond well established source categories (e.g., nitrogen oxide emissions from automobiles, or nitrous oxide emissions from adipic acid production).

CARBON

Anthropogenic emissions of carbon arise predominantly from the combustion of fossil fuels, the burning of biomass, as well as oxidation of soil carbon following land-use changes (e.g., deforestation). These anthropogenic emissions are embedded in large fluxes between the (yet larger) carbon reservoirs (atmosphere, oceans, vegetation and soils, as well as deposits of fossil fuels) that characterize the carbon cycle (Houghton and Skole, 1990; Schimmel *et al.*, 1995, *see* Carbon Cycle, Volume 2). Due to the magnitude of the reservoirs and the annual exchange rates between them, that are known only approximately, human alterations to the carbon cycle are comparatively

small, are difficult to quantify and are hence subject to considerable uncertainties, especially for land-use change carbon emissions.

The Intergovernmental Panel on Climate Change (IPCC) summarizes current knowledge on the size of the respective carbon reservoirs and fluxes for the 1980s as follows (Schimmel *et al.*, 1995; Nakicenovic *et al.*, 1996): the largest carbon reservoirs are the oceans (close to 40 000 Pg C [Pg C = Petagrams (10^{15} g) elemental carbon, 1 Pg = 1 Gt (gigatons, or one billion metric tons), 1 Pg = 1000 Tg (teragrams, or 10^{12} g)]), deposits of fossil fuels (coal, conventional and unconventional oil and gas (such as *inter alia* oil shales, tar sands, gas in tight formations, in aquifers, and coal seams), including methane hydrates: 25 000 Pg C), vegetation and soils (2200 Pg C), and finally the atmosphere (750 Pg C). Only the latter carbon reservoir size is directly measurable, and the increasing atmospheric carbon dioxide concentrations are proof that human activities and resulting emissions are indeed altering the carbon cycle, the composition of the atmosphere, and hence the radiative (heat) balance of the planet (global warming). The global carbon cycle involves the annual exchange of some 90 Pg C between the atmosphere and the oceans, and some 60 Pg C between the biosphere (vegetation and soils) and the atmosphere. The inter-annual variations of measured atmospheric carbon dioxide concentrations (5.4 parts per million by volume (ppmv) in 1998 at Mauna Loa, Hawaii (Keeling and Whorf, 1999)) clearly indicate the importance of seasonal vegetation cycles in biospheric carbon fluxes. The inter-annual variation of 5.4 ppmv corresponds to some 11 Pg C. Compared to the size of annual fluxes that characterize the carbon cycle and its inter-annual variations, anthropogenic alterations to the carbon cycle are comparatively small and hence impossible to measure directly. Emission estimates need therefore to be based on inventory data linking socio-economic activity data such as fossil fuel use or land use changes, with specific emission factors in the case of fossil fuel emissions, or micro- and meso-scale models of how soil and vegetation carbon reservoirs, and the exchange rates between them, are affected by human activities.

Currently (AD 2000), human-induced alterations to carbon flows include emissions of some $6.6(\pm 0.6)$ Pg C year^{-1} from industrial activities (mostly the burning of fossil fuels) that constitute a net addition to natural carbon fluxes, albeit not necessarily in the same year. In addition, estimates indicate a net additional flux of about one (uncertainty range: 0 2.8) Pg C year^{-1} from the burning of biomass and changes in soil carbon in conjunction with land use changes. This estimated net biospheric flux is the difference between estimates of a variety of carbon sources and sinks (see discussion below) and is affected by high uncertainty margins. This is illustrated in the following simplified representation of the global annual carbon balance in Pg C for the 1980s (Schimmel *et al.*, 1995; Houghton, 1999).

$$\begin{aligned}\text{atmospheric increase} &= \text{industrial emissions}\\ &\quad + \text{net land-use emissions} - \text{ocean uptake}\\ &\quad - \text{residual (missing sink)}\\ 3.3(\pm 0.2) &= 5.5(\pm 0.5) + 1.1(0 - 2.8) - 2.0(\pm 0.8)\\ &\quad - 1.3(0 - 3.3)\end{aligned}$$

Table 1 summarizes the main, contemporary anthropogenic industrial and biotic carbon emission sources as well as associated uncertainty ranges. The numbers exclude carbon dioxide fluxes arising from the metabolism of human and animal populations for which inventory data are lacking.

Industrial sources of carbon emissions are comparatively well understood and quantified. The dominant source is fossil energy production, conversion, and use, i.e., burning of fossil fuels (6 Pg C). Secondary sources are the manufacture of cement (0.2 Pg C) and the flaring of natural gas (0.06 Pg C) which occurs when gas is produced together with crude oil, but due to the absence of local markets or infrastructures cannot be used as a fuel and is flared (burned) instead. Re-injection into the oil reservoir for repressuring avoids the need for flaring and is practiced in many oil fields (CEDIGAZ, 1998). Yet even the modest costs involved seem not to justify the preservation of natural gas resources for future uses in many locations. Hence flaring continues (albeit declining). Globally some 120 billion m^3 of natural gas are flared, about equal to the global trade in LNG (liquefied natural gas) or the natural gas consumption of Germany, Austria, Switzerland, and Belgium combined (CEDIGAZ, 1998). Minor carbon emission sources include the manufacture of lime and ammonia (Harvey, 1999), the release of carbon dioxide from carbon dioxide rich fossil fuel reservoirs, and the production of carbon dioxide from natural reservoirs for tertiary oil recovery and for the food (beverage) industry. Even if small when compared to natural carbon fluxes, carbon emissions are the largest material flow of the industrial metabolism. The 6 Pg C of industrial carbon emissions compares, for instance, to an annual production volume of 2.5 Pg for the seven most important industrial commodities (in decreasing order of tonnage: cement, steel, paper, fertilizers, glass, aluminum, copper, cf. Grubler, 1998a).

Emission estimates for industrial sources are quite accurate ($\pm 10\%$). As energy is a preferred target for taxation, production, trade, and stock statistics are fairly accurate, at least for commercially traded energy forms such as fossil fuels. (Uncertainties for non-commercial energy use such as the traditional biomass fuels used in developing countries are however substantial (*see* Biomass Burning in Rural Homes in Tropical Areas, Volume 3).) The net balance between production, trade flows and stock changes allows one to determine annual apparent fossil

Table 1 Global carbon emissions as estimated for 1990 per major source category and uncertainty ranges (in Tg C year^{-1})[a]

		Net	Gross	Uncertainty range
	Coal	2424		
	Oil (fuels)	2285		
	Oil (feedstocks)		324	
	Gas	1135		
	Cement	157		
	Gas flaring	60

	Fuelwood[b]		530	
	Traditional biofuels[b]		630	
Biofuels[b]			1160	??–1600
	Savannah fires[c]		1660	
Other biomass				??–1700
	Tropical forests[d]		1100	
	Temperate forests[d]		0	
Land-use change[b]			1100	0–2800[e]
Total		6061	8645	5800–>13 100

[a] Emission categories that are not balanced by (uncertain) biospheric carbon sinks or that are not released to the atmosphere in the same year are listed as gross emissions, all others as net emissions (see text). For land-use change related emissions, the net biospheric flux as estimated by IPCC (1995) for the 1980s (the latest period for which global estimates are available) and the uncertainty range as estimated by Houghton (1999) for the same period are given. (Data source: see text.)
[b] Emissions of biofuels and land-use change not necessarily entirely additive.
[c] Andreae (1991). Not included in total gross emissions.
[d] Estimated net biospheric flows (IPCC, 1995).
[e] Upper range for net biospheric flux due to land-use change (Houghton, 1999), no estimates of gross emissions available.

fuel consumption, and that combined with carbon emission factors makes quantification of corresponding carbon emissions rather straightforward. Emission estimates are made regularly from the energy statistics of the United Nations (Marland *et al.*, 1999), the International Energy Agency (IEA, 1998), or the statistics published by British Petroleum (BP, 1999, see Table 1) drawing on similar methodologies (for the IPCC/IEA guidelines, see Houghton *et al.*, 1996). Aggregate results yield comparable global numbers, albeit differences (i.e., uncertainties) remain in the partition between various fuel types and between regions as a result of statistical differences and uncertainties in the heat content of different fuels, especially for coal. As an approximation, carbon emission factors are practically constant per unit energy content for different qualities of fuelwood, coal, oil, and gas, respectively, reflecting their molecular composition (ratio of hydrogen to carbon atoms). Characteristic emission factors (based on lower heating values) are 29.9 kg C GJ^{-1} for fuelwood (and other biomass fuels), 25.8 kg C GJ^{-1} for coal, 20 kg C GJ^{-1} for oil, and 15.3 kg C GJ^{-1} for gas (Nakicenovic *et al.*, 1996). Hence, uncertainties in heat values of different fuel qualities translate into proportional uncertainties of carbon emissions. Emission estimates for non-energy uses of fossil fuels (feedstocks) are affected by larger uncertainties, as the carbon contained in feedstock fuel (mostly oil) ends up in a wide variety of products (plastics, asphalt, bitumen, lubricants) which are in many instances long lived. Several decades may therefore pass before the carbon contained in these products is ultimately oxidized (e.g., when these products are burned) and released to the atmosphere. Hence, for any given year, it is necessary to distinguish between gross and net emissions. *Gross emissions* result from the transfer of carbon between various reservoirs due to human activity such as converting crude oil extracted from an oilfield where it has remained for geological ages to combustible fuel (e.g., gasoline) or long-lived materials (e.g., plastics, asphalt). *Net emissions* of any given year are those that result from human activities in that year, e.g., burning of gasoline in an internal combustion engine car. For fossil fuel, the differences between gross and net emissions are comparatively minor: some 0.3 Pg C, or 5%. Yet the difference is of similar importance as the secondary industrial sources i.e., cement manufacture and gas flaring.

Another source of uncertainty relates to biomass fuels. When produced at sustainable rates, sources and sinks will balance, albeit not necessarily in a given year. Whenever, biomass regrowth falls short of the rate of biomass burning, sources exceed sinks, giving rise to net emissions. Historically, this was the case for industrialized countries. Recently, biotic sinks have exceeded biotic emissions in the Northern Hemisphere, justifying the classification of biofuels as *carbon neutral*. The current situation in many developing countries is far removed from this carbon

benign state of affairs, resembling that in the industrialized countries some decades to a few centuries ago, characterized by deforestation and unsustainable biomass fuel use. The historian of pre-industrial Europe Carlo Cipolla (1981) characterizes medieval European forestry use as eminently parasitic and extremely wasteful . Biomass fuels are therefore included in the biotic carbon sources given in Table 1 as they usually are accounted for in detailed land-use change carbon inventories (Houghton, 1999). Note however, that the values given for gross emissions of biomass burning (e.g., fuelwood) and those from land-use changes are not necessarily additive because fuelwood gathering in connection with deforestation is usually also accounted for in the respective land-use change related carbon uxes. Thus, part (perhaps up to 0.5 Pg C) of the 1.2 Pg C gross emissions due to biofuel burning may already be included in the 1.1 Pg C gross emissions due to land-use changes reported in Table 1. This uncertainty and the risk of possible double counting has led to the doubtful practice of generally ignoring biofuel related carbon emissions in energy studies and emission inventories.

Differences between gross and net emissions as well as uncertainties are especially pronounced in the case of biotic carbon emissions. In that case, gross emissions, e.g., from biomass burning, need to be balanced with corresponding sinks, i.e., the uptake of carbon dioxide by vegetation in order to determine net emissions. In addition, both sources and sinks operate frequently on different time scales (burning a wood log takes an hour, growth of a tree many decades). To complicate things further, changes in vegetation cover also involve changes in soil carbon. The response rates of top and deep soil layers to a change in vegetation cover (e.g., conversion of forests to agricultural elds) are poorly understood and involve time scales of many decades (Houghton and Skole, 1990; Houghton, 1999).

Consider the burning of agricultural residues either in the eld or as energy for rural households: emissions from biomass grown on an annual rotational cycle are balanced by corresponding vegetation regrowth (carbon uptake) in the following or preceding growing season. A similar case is that of savannah res (natural or induced by human activities). Combined, these two categories involve the annual burning of some 5.7 billion tons dry matter per year and an estimated release of 1.6 Pg C (Andrae, 1991, see Table 1). As sources and sinks are assumed to balance over a time scale of approximately a year, these emission categories are generally excluded from carbon inventories (and are also not shown in the Figures below, not the least because historical estimates are unavailable. An exception is biomass fuel outside fuelwood, for which a conservative estimate is included in the data presented here (based on interpolated values given in UN, 1952; Putnam, 1954; Nakicenovic *et al.*, 1998. As simpli cation, the carbon emission factor for these other traditional biofuels like agricultural residues, dried animal dung, etc., is assumed to be the same as fuelwood).

For a complicated case consider the case of forest clearing: Felling of trees may entail short-term carbon emissions when wood is used as fuel, and a signi cantly delayed response when used as construction material (when a wood structure eventually burns down). In most cases, the dominant source of carbon emission is the decay of woody material after forest clearing (Houghton *et al.*, 2000). Carbon releases from soils depend critically on the ensuing land uses: secondary forest regrowth, or conversion to intensive agriculture. Soil carbon release rates depend therefore on (changing) land uses that follow deforestation and involve a time scale of many decades. Estimating corresponding carbon uxes is thus a formidable challenge.

Large uncertainties thus prevail for biospheric carbon sources and sinks. Assuming high biospheric (gross) emissions implies assuming a large biospheric sink (frequently assumed to be located in northern latitudes, cf. Schimmel *et al.*, 1995) in order to balance the global carbon cycle. Low biospheric emission uxes, especially when combined with upper range estimates of oceanic uptake rates, reduce the size of the residual (missing) sink required to balance the global carbon cycle. The average value of 1.1 Pg C year^{-1} net biospheric carbon emissions for the 1980s suggested in the IPCC review (Schimmel *et al.*, 1995) is derived from adopting a mean value of 1.6($\pm$1) Pg C from tropical latitudes balanced against an estimated uptake rate of 0.5($\pm$0.5) Pg C year^{-1} for northern latitudes. The estimated net biospheric ow of 1.1 Pg C represents a top down estimate, based on balancing the global carbon cycle as well as on carbon cycle model calculations. These models are frequently initialized with a 1980s global biospheric ux of 1.1 Pg C when reproducing the historical record of carbon dioxide concentration changes or when calculating future scenarios (for an overview see Houghton *et al.*, 1997; for a representative model see e.g., Wigley *et al.*, 1994).

Conversely, bottom-up assessments based on detailed inventory models, that yield changes in vegetation and soil carbon in response to land-use changes, typically yield higher estimates of net biospheric carbon ows: 2($\pm$0.8) Pg C year^{-1} for the 1980s, including 1.9($\pm$0.6) Pg C in the tropics and 0.1($\pm$0.5) Pg C in temperate latitudes (Houghton, 1999). Available (uncertain) forest inventory data indicate an average rate of tropical forest clearing of some 13.3 million ha year^{-1} for the 1980s, and an average 12.6 million ha year^{-1} for the period 1990 1995, compared to an average afforestation rate of 1.3 million ha year^{-1} in non-tropical regions for the period 1990 1995 (FAO, 1997; WRI, 1998). Translating these land-use change numbers into estimates of gross biospheric emissions and balancing those against sinks to determine estimates of net emissions

is highly problematic because of uncertainties in secondary forest regrowth, soil carbon, as well as the magnitude of the (undisturbed) forest carbon sink. Recent estimates for the Brazilian Amazon, characterized by high rates of forest clearing and regrowth (*see* **Deforestation and Habitat Fragmentation in the Amazon Basin**, Volume 3), conversion to agricultural uses followed by later abandonment, and wood logging, indicate nonetheless a roughly balanced carbon budget between emissions due to land-use changes and carbon uptake by vegetation regrowth and by natural ecosystems in the region (Houghton *et al.*, 2000). However, considerable variations exist between individual years: the Brazilian Amazon is estimated to have been either a (net) source or sink of about 0.2 Pg C for different individual years over the period 1989 1998.

Whereas bottom-up assessments thus continue to be the best way for estimating current and historical gross biotic carbon emissions, it is not possible yet to accurately determine net biospheric carbon emissions. This is why no estimates of respective current net emissions are given in Table 1. Also in the figures of historical emissions given below, respective biospheric carbon emissions are reported as gross values only.

From a combination of direct atmospheric measurements and analyses of air samples trapped in glacier ice, there is compelling evidence that atmospheric carbon dioxide concentrations have increased from some 280 ppmv (Neftel *et al.*, 1985; Schimmel *et al.*, 1995) in pre-industrial times to some 370 ppmv (estimate for AD 2000): i.e., an increase in the atmospheric carbon reservoir of close to 200 Pg C over the last 200 years. How can this increase in atmospheric concentration be allocated to different carbon emission categories?

Historical emission inventories for fossil fuel use and other industrial sources have a long scientific history starting from the pioneering contributions of Putnam (1954) and Keeling (1973). For land-use related emissions, the main historical data sources are the estimates of Houghton and Skole (1990) and Houghton (1999). A combined historical inventory of industrial and biotic carbon emissions was developed by Grubler and Nakicenovic (1994), an update of which is summarized in Figures 1 and 2. The original inventory spanned the period 1800 1988. Updates for fossil fuels, cement and gas flaring to 1998 are based on BP (1999) (and earlier vols.), CEDIGAZ (1998); and Marland *et al.* (1999). Values for the year 2000 are estimates based on extrapolation of short-term (1995 1998) trends. For biotic emissions, a comparable value as estimated by the IPCC (Schimmel *et al.*, 1995) for the 1980s, i.e., average annual net biotic emissions of 1 Pg C, was assumed for the 1990s, based on FAO (1998) forest inventory data that indicate similar average deforestation rates in the two time periods.

Figure 1 presents an overview of historical carbon emissions by source since 1800. Figure 2 adds these emissions categories, presenting them as cumulative totals. Only emissions from burning of fossil fuels and from the manufacture of cement can be classified clearly as net contributions to the atmosphere. As discussed above, the fraction of gross emissions that is not absorbed by sinks, or that may be released over long time periods (feedstocks) is highly uncertain. Hence these emission categories are shown as

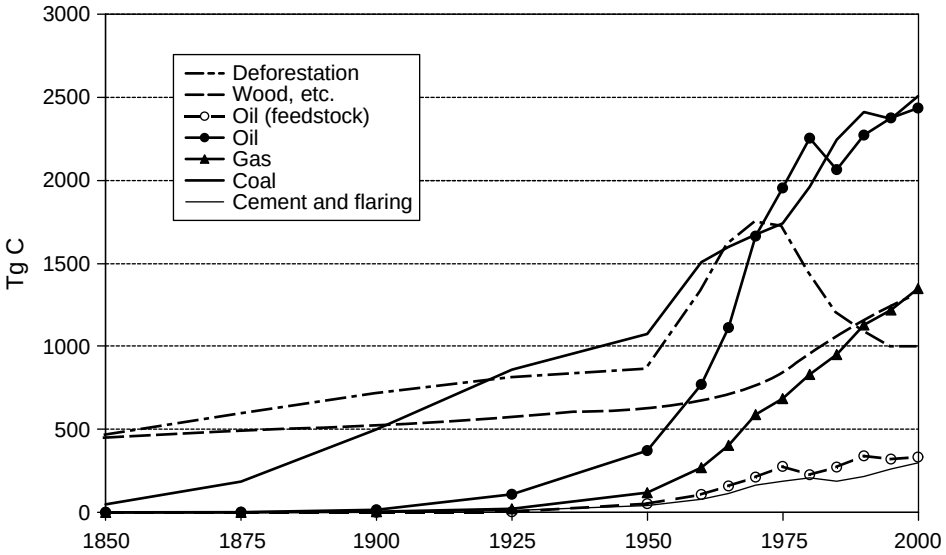

Figure 1 Annual carbon emissions per major source category 1850–2000 (in Tg C year^{-1}). Emission categories that are not balanced by (uncertain) biospheric carbon sinks or that are not released to the atmosphere in the same year are shown as gross emissions (dashed lines), all others as net emissions (solid lines). Values for the year 2000 are preliminary estimates. (Reproduced from Grübler and Nakicenovic, 1994 and Grübler, 1998a [Updated (see text)])

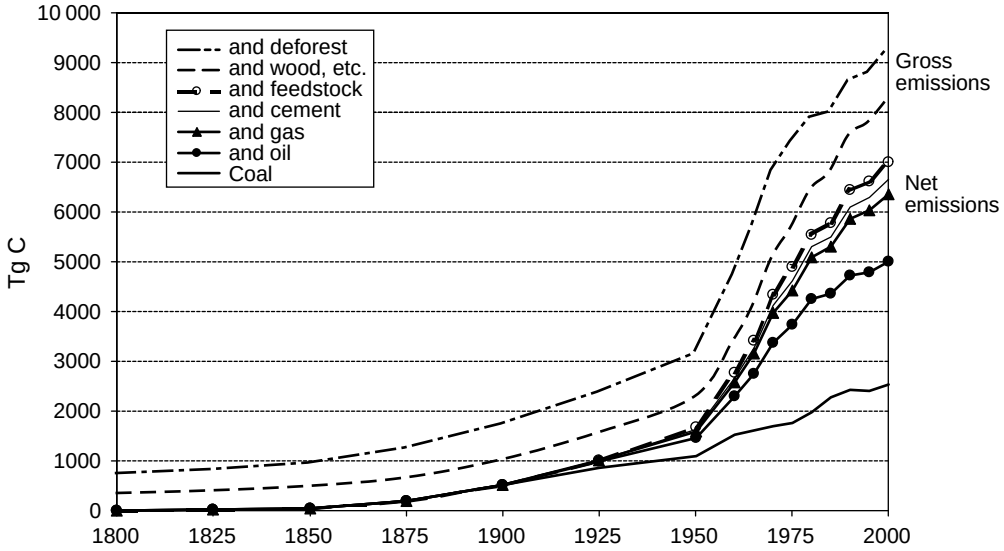

Figure 2 Annual carbon emissions per major source category 1800–2000, cumulative totals (in Tg C year^{-1}). (Reproduced from Figure 1)

gross emissions only in Figure 2. Cumulatively over the period 1800 2000, net carbon emissions total (a minimum) of some 280 Pg C, whereas gross carbon emissions total (a maximum) of 530 Pg C. In explaining the growth of atmospheric carbon, net emissions need to be balanced against the magnitude of the oceanic carbon sink, whereas gross emissions need to be balanced against the size of both the oceanic and the terrestrial carbon sinks.

In order of decreasing importance in terms of cumulative emissions since 1800 (derived from Figures 1 and 2), burning of coal and emissions due to land use changes are the two most important emission categories (148 Pg C net for coal and 155 Pg C gross for land-use changes). Houghton (1999) estimates for the period 1850 1990 that land-use changes (including fuelwood burning and logging) released a total of 373 Pg C to be balanced against an estimated terrestrial sink uptake of 249 Pg C (211 Pg C carbon uptake by vegetation regrowth and 38 Pg C soil carbon recovery). This yields an estimated net biospheric carbon flux of 124 Pg C, a comparable magnitude to the 155 Pg C gross carbon emissions due to land-use changes (excluding fuelwood burning) estimated here for the period 1800 2000. Oil ranks third (91 Pg C net emissions or 103 Pg C when non-energy feedstock uses (12 Pg C), classified here as gross emissions, are added). Burning of fuelwood and other (traditional) biomass fuels for energy purposes is estimated to have released some 77 Pg C (gross) emissions, albeit this quantity is not necessarily entirely additive to the emissions estimated from land-use changes. Burning natural gas as fuel is estimated to have released some 38 Pg C (net) since 1800 (most of it since 1950), whereas the manufacture of cement and the flaring (waste) of natural gas yields a comparatively small number of 5 Pg C (net) emissions since 1800.

Thus, the historic atmospheric increase of some 200 Pg C balances against a range of between 280 and 530 Pg C (net/gross) carbon emissions from all sources and an inferred cumulative uptake by all carbon sinks (oceanic and terrestrial) of between 80 and 330 Pg C over the period 1800 2000.

Most of the historical human-induced perturbations of the global carbon cycle originate from emissions in the industrialized countries. From the estimated cumulative net carbon emissions since 1800 (some 280 Pg C), about three-quarters originate from the industrialized countries, and one quarter from developing countries. For gross emissions, the difference is less pronounced: about 55% originate from the industrialized countries versus 45% from developing countries. Yet, such comparisons of historical emissions ignore important regional disparities in emission drivers such as population, levels of affluence, and levels and efficiency of technologies employed. When making these comparisons, it must be remembered that since 1800 70% of the world s people have lived in the developing countries (Grubler and Nakicenovic, 1994). Therefore when measured on a *per capita* basis the share of developing countries in historical or current emissions is much smaller than the simple numbers above would suggest (for detailed calculations see Fujii, 1990; Grubler and Fujii, 1991).

The division of annual gross and net emissions since 1800 for three macroregions is illustrated in Figure 3. The definition of these three macroregions follows that of the original UN Framework Convention on Climate Change (UNFCCC, 1992). It comprises: the countries of the OECD as of 1990 (Annex II in United Nations Framework Convention on Climate Change (UNFCC)); the countries of Central and Eastern Europe as well as of the

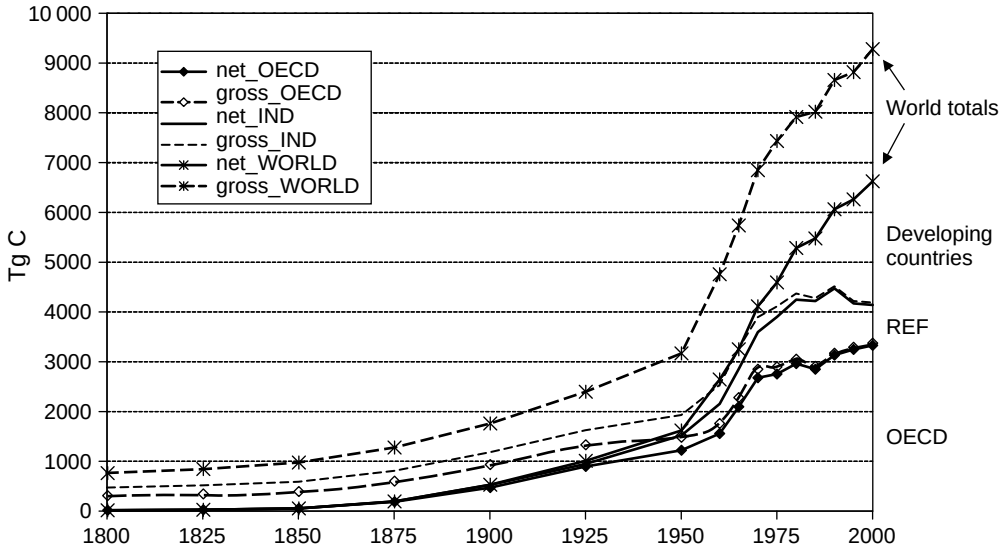

Figure 3 Annual carbon emissions per major emitting regions and given as cumulative totals (in Tg C year^{-1}). The regions are as defined in the 1990 UNFCC (*see* **United Nations Framework Convention on Climate Change and Kyoto Protocol**, Volume 4): OECD countries as of 1990 (OECD, UNFCCC Annex II countries), countries undergoing economic reform (REF, UNFCCC Annex I countries outside Annex II), and developing countries (DEV, UNFCCC non-Annex I countries). OECD and REF combined represent the industrialized countries referred to in the UNFCC as Annex I countries (IND in Table 3). Respective totals for gross and net carbon emissions (all sources) are shown as dashed and solid lines respectively (see text). (Reproduced from Grübler and Nakicenovic, 1994 [updated (see text)])

former Soviet Union undergoing economic reform (Annex I outside Annex II in UNFCC); as well as developing countries (non-Annex I countries in UNFCCC). Combined OECD and economic reform countries constitute the industrialized countries (IND in Figure 3) as defined by Annex I of the 1992 UNFCCC (*see* United Nations Framework Convention on Climate Change and Kyoto Protocol, Volume 4).

It is important to note that differences between gross and net emissions for different regions change over time. For instance, whereas this difference is substantial for the industrialized countries throughout the 19th century and also up to approximately 1950, the difference gets smaller, gradually disappearing after the 1970s. In other words, biotic carbon emissions such as land-use changes and fuelwood use (the main source for the difference between gross and net emissions shown in Figure 3), while being important in the early history of industrialization, are no longer important in the industrialized countries. There, the dominant emission source at present is the burning of fossil fuels. Currently, biotic carbon emissions in industrialized countries are close to zero. Historically, they account for about one quarter of cumulative carbon emissions of the industrialized countries since 1800. For developing countries, the situation resembles that of the industrialized countries more than a century ago (when the industrial countries had similar (low) levels of *per capita* incomes as the developing countries have today): an important share of emissions comes from biotic sources, with fossil fuel shares increasing in importance over time. Industrial emission sources account for around 40% of cumulative emissions of developing countries since 1800; by the year 2000 they already account for two thirds of carbon emissions from developing countries.

A brief discussion of how to relate the historical trends in emissions discussed above to main driving forces is given at the end of this contribution using energy-related carbon dioxide as example (*see* Carbon Dioxide Concentration and Climate Over Geological Times, Volume 1; Carbon Dioxide, Recent Atmospheric Trends, Volume 1; Carbon Cycle, Volume 2; Boreal Forest Carbon Flux and it s Role in the Implementation of the Kyoto Protocol Under a Warming Climate, Volume 4).

Concerning future emission trends, the (vast) literature on this subject cannot be reviewed in detail here. A comprehensive, quantitative overview of the scenario literature is given by Nakicenovic *et al.* (2000), who also present the latest long-term emissions scenarios developed under the auspices of the IPCC. In this scenario set, representative of current understanding of the underlying uncertainties in demographic, economic and technological developments, global carbon emissions could range anywhere between 8 and 27 Pg C by 2050 and between 3 and 37 Pg C by the end of this century. It is also instructive to look at projected levels of cumulative emissions, which are a (rough) first approximation of the possible magnitude of climate change. By 2100 cumulative carbon emissions could range between 770 and 2540 Pg C, or between equal, to more than three

times the amount currently contained in the atmosphere. In the absence of vigorous climate change policy initiatives (the new IPCC scenarios were developed under the mandate of explicitly excluding additional climate policies) even the lowest scenarios suggest that more carbon will be released to the atmosphere over the next 100 years (>770 Pg C) than has cumulatively been released since the onset of the Industrial Revolution (range of 230 530 Pg C net/gross emissions since 1800, respectively). A significant amplification of humankind s discernible influence on the climate system (IPCC, 1995) is thus likely.

SULFUR

Studies of the global sulfur cycle (good reviews are provided by Husar and Husar, 1990; and Smil, 1997) indicate that anthropogenic emissions of sulfur have surpassed natural flows ever since the first quarter of the 20th century. Dominant natural sources include the weathering of rocks and soil, volatile biogenic sulfur emissions from land and the oceans as well as volcanoes. Combined, natural sources are estimated to release between 40 and 60 Tg S (1 Tg S = one million (metric) tons elemental sulfur (MtS). To convert to SO_2, the customary unit of most sulfur studies, multiply by 2 (IPCC, 1995; Husar and Husar, 1990). This compares to total anthropogenic sulfur emissions of between 65 and 90 Tg S in the early 1990s (Benkovitz *et al.*, 1996; Olivier *et al.*, 1996; WMO, 1997). The dominant form of anthropogenic sulfur emissions is airborne emissions of SO_2 with some smaller quantities of SO_3 (hence sulfur emissions are frequently referred to as SO_x).

The ecological impacts of large anthropogenic sulfur emissions arise at three spatial and temporal scales. First, at the local level, high ambient concentrations of SO_2 have well documented (WHO and UNEP, 1993; WMO, 1997) impacts on human health, vegetation, and materials (corrosion, stone cancer of historical sandstone buildings). Second, sulfur emissions are one of the main contributors to acidic deposition (acid rain) that affects ecosystems up to a continental scale (changes in pH of streams and lakes and resulting decline in fish populations, reductions in the vitality of the forest ecosystem. Forest dieback, or Waldsterben however is increasingly recognized as a multiple stress phenomenon that cannot be related simply to a single source of environmental stress such as acidic precipitation) (*see* Waldsterben, Volume 5). Typically, impacts accrue in a highly non-linear fashion (dependent on acidic deposition levels and the buffering capacity of soils) which have led to the formulation of *critical loads* of acidic deposition (see e.g., Amann *et al.*, 1995; Posch *et al.*, 1996) (*see* Critical Load, Volume 3). Thirdly, sulfur emissions also assume global ecological significance; evidence is increasing that sulfate aerosols exert a pronounced cooling effect (counterbalancing greenhouse gas (GHG)-induced warming) in the Northern Hemisphere (IPCC, 1995).

A detailed review of available sulfur emission inventories is given in Grubler (1998b), where available global sulfur emission inventories are also compared for the year 1990. The best-guess value suggested in that review is 76 Tg S global anthropogenic sulfur emissions for 1990.

The dominant anthropogenic sources of sulfur emissions are (as for carbon emissions) the burning of fossil fuels. In the case of sulfur, emissions are dominated by burning of coal (some 53 Tg S in 1990, Lefohn *et al.*, 1999) and to a smaller degree by oil products (12 Tg S). Natural gas is (with a few exceptions that do not assume any global significance) almost sulfur free (small traces of sulfur compounds (H_2S) are added deliberately as a safety measure; a smelly tracer helps to detect gas leakages) and hence not a significant source. The third largest emissions category is metallurgical processes (reduction of sulfide ores during the smelting of copper, lead, and zinc), estimated at some 6 Tg S in 1990 (Lefohn *et al.*, 1999). Smaller additional emissions sources are biomass burning (some 2 Tg S, cf. Pepper *et al.*, 1992), as well as marine bunker fuels (usually high sulfur-containing heavy fuel oil which is generally not allowed to be burned on land) with some 3 Tg S in 1990 (4 Tg S in 1994, cf. Corbett *et al.*, 1999). Finally, sulfur emissions from pulp and paper mills, although globally marginal, may have important local ecological effects (apart from their offensive smells). For the sake of completeness, it also should be mentioned that the elemental sulfur mined (some 25 Tg S, Smil, 1997) as feedstock for the chemical industry (mostly used in the production of sulfuric acid) generally does not result in airborne emissions. This market however, is declining with the increasing availability of elemental sulfur recovered in oil refineries as a byproduct of fuel desulfurization to meet environmental standards (likewise gypsum mining faces increasing competition from gypsum produced from flue gas desulfurization units of coal-fired power stations).

Sulfur emission inventories are developed on a regular basis in a number of regions, including within the EMEP and CORINAIR programs in Europe and the National Acid Precipitation Assessment Program (NAPAP) in North America. Recently more detailed emission inventories have become available for Asia, where emission growth rates are particularly high (Streets *et al.*, 2000), including work in conjunction with the World Bank sulfur project (Foell *et al.*, 1995), and the detailed bottom up estimates of Akimoto and Narita (1994) and Kato (1996). Sulfur emissions in all regions not mentioned above (i.e., Pacific OECD countries like Australia and New Zealand, and all developing countries outside Asia) are much less well studied. Even if presently small when compared to those of Europe, North America and Asia, the sulfur emissions in these regions are likely to grow significantly in the longer-term.

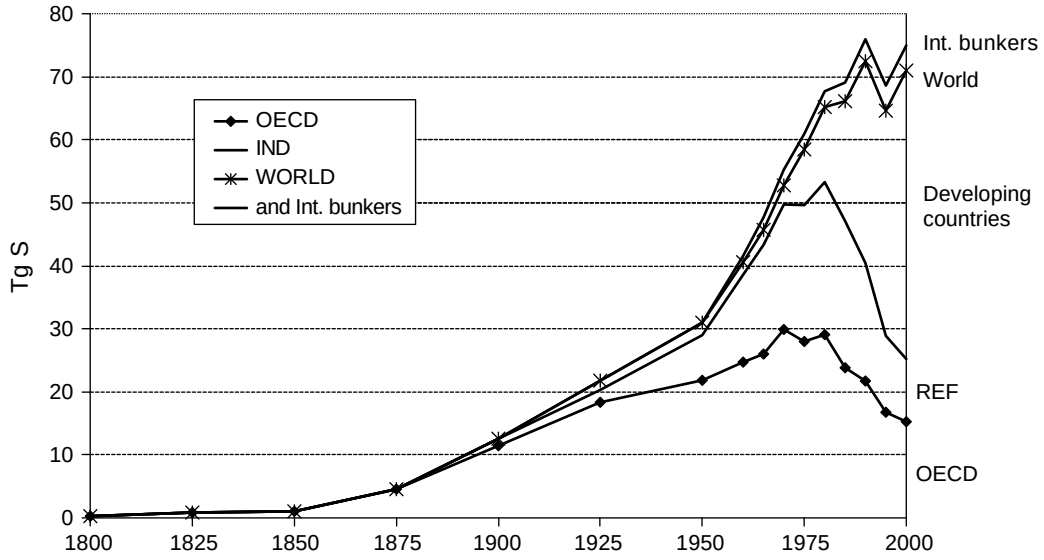

Figure 4 Annual sulfur emissions per major emitting region as defined in Figure 3, 1800–2000, shown as cumulative totals (in Tg S year^{-1}). Emissions from international marine bunker fuels that are usually not accounted for in national/regional emission inventories are shown separately. (Data sources: see text)

At the global level, a number of spatially detailed sulfur emission inventories have been developed. Global, gridded (1×1 degrees) sulfur emissions inventory data are needed for a variety of purposes, most notably for climate modeling purposes. As a rule, the required cycle times for the development of such detailed inventories are rather long, implying that data can be quite outdated. With the exception of the EDGAR data base (Olivier *et al.*, 1996) referring to 1990, global gridded data sets available are quite outdated in view of rapidly changing regional sulfur emission trends. For instance, the Spiro *et al.* (1992) inventory refers to the year 1980; the Global Emissions Inventory Activity (GEIA) (Benkovitz *et al.*, 1996) gridded sulfur emission data are an update of the Spiro *et al.*, data set for 1985 for a number of regions, most of them OECD countries, but retain 1980 values for many countries and regions.

Contrary to carbon emissions, global and regional sulfur emission trends are much more dynamic, particularly since the early 1970s. As a result of sulfur abatement efforts, emissions in the OECD countries, particularly in Europe and Japan have declined drastically. Emissions in Central and Eastern Europe as well as the successor states of the former Soviet Union have also declined, especially in the wake of their economic restructuring. Conversely, with accelerated economic development, the growth of sulfur emissions in many part of Asia has been fast, albeit growth rates have declined recently (Streets *et al.*, 2000). Thus sulfur emission trends must be analyzed regularly and with as recent data as possible.

Historical sulfur emission inventories were first developed for Europe (cf. the formidable historical work of Mylona, 1993, 1996) as well as for the US (Gschwandner *et al.*, 1985; EPA, 1995). Global estimates have been developed by Dignon and Hameed (1989); Stern and Kaufmann (1996) and Lefohn *et al.* (1999). A synthesis of these long-term sulfur emission trends is given in Figure 4.

The long-term pattern of global sulfur emissions is characterized by three phases: First until about the 1920s, sulfur emissions rose very rapidly (at an estimated average annual growth rate of some 4% year^{-1}) with the expanding use of coal, the fossil fuel richest in sulfur. In the period 1925 to ca. 1975, growth in global emissions continued, albeit at slower rates (some 2% year^{-1} on average), as coal increasingly was replaced by oil, generally lower in sulfur content. Since around 1975, global emissions have stayed roughly constant. The continued rise of sulfur emissions in developing countries has been compensated by the drastic declines in emissions in the OECD countries (first Japan, then Europe and North America) as a result of environmental policies leading to fuel substitution, fuel desulfurization as well as stack gas cleaning (scrubbing). Emissions in Central and Eastern Europe, as well as in the successor states of the former Soviet Union, have also declined drastically as a result of replacement of coal by other fuels, as well as the drastic economic recession since the early 1990s (the effects of environmental control measures like flue gas desulfurization have been more limited to date). The industrialized countries accounted with some 50 Tg S for well over 80% of global sulfur emissions in 1975. By 2000, their sulfur emissions were down to some 25 Tg S (33% of global emissions), whereas those of the developing countries (mostly in Asia) have risen to some 50 Tg S (around 67% of global emissions).

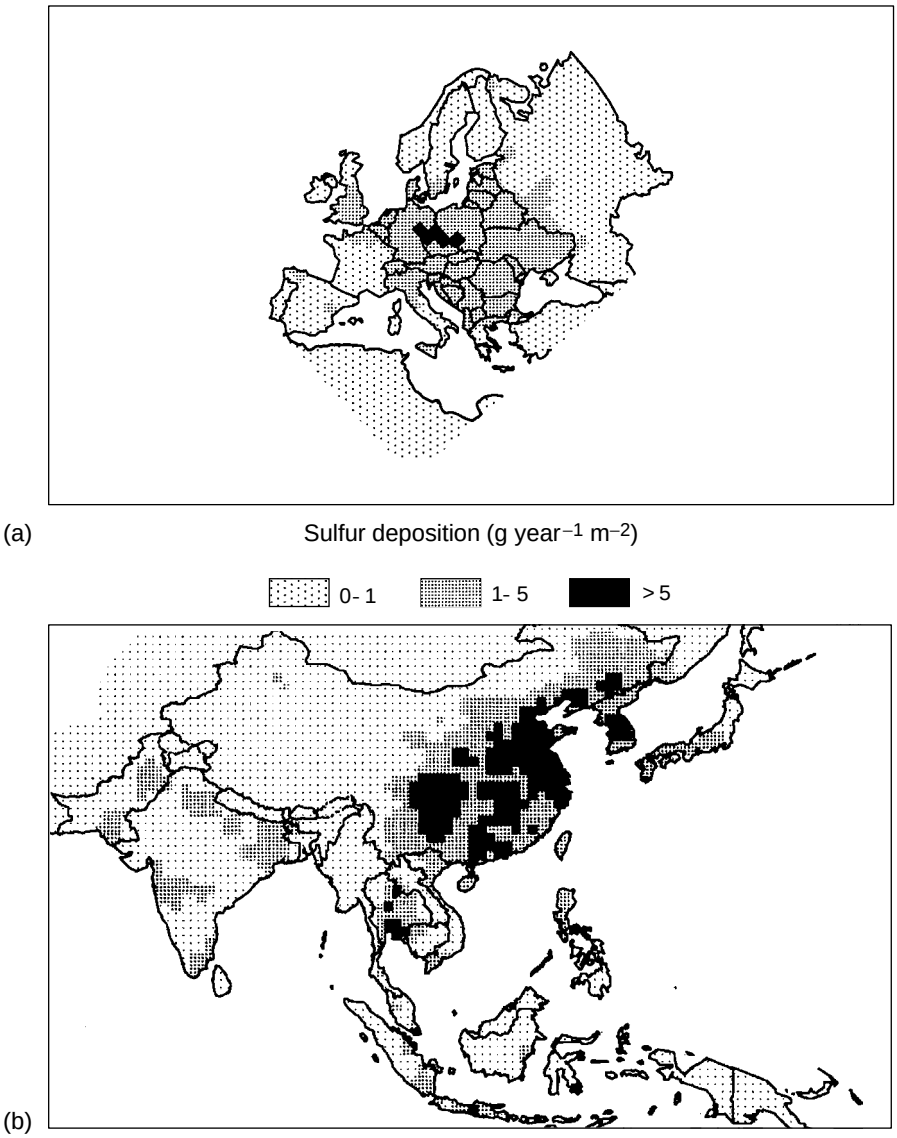

Figure 5 Extent of likely peak sulfur deposition levels: 1990 sulfur deposition in Europe (a) and projection for an (unabated) high-growth scenario for Asia in 2020 (b), in grams sulfur (S) m^{-2}. (Reproduced from Grübler, 1998a based on Amann *et al.*, 1995)

Recent estimates for Asia (Streets *et al.*, 2000) indicate however, that also there, emission growth rates are declining as a result of the introduction of sulfur control legislation (Grubler, 1998b; IEA, 1999; Nakicenovic *et al.*, 2000; Streets *et al.*, 2000). An acceleration of these trends seems highly desirable in view of the projected large-scale impacts on human health, food production, as well as ecosystems of unabated growth in sulfur emissions in the densely populated, coal intensive economies in Asia. A representative result of such projected scenarios (based on Amann *et al.*, 1995) is shown in Figure 5, which contrasts 1990 European sulfur deposition levels with those of Asia by 2050 in a high (unabated) sulfur emission scenario. Typically, in such scenarios, sulfur emissions in Asia alone could surpass current global levels as early as 2020 (Amann *et al.*, 1995; Posch *et al.*, 1996). Sulfur deposition above $5\,g\,m^{-2}\,year^{-1}$ occurred in Europe in 1990 in the area of the borders of the Czech Republic, Poland, and Germany (the former GDR); often referred to as the black triangle . In view of its ecological impacts, it was officially designated by the United Nations Environment Programme (UNEP) as an ecological disaster zone . In the scenario of high sulfur emission growth in Asia illustrated in Figure 5, similar high sulfur deposition would occur by around 2020 over more than half of Eastern China, large parts of southern Korea, and some smaller parts of Thailand and southern Japan.

In order to avoid excessive damages, sulfur controls similar to those used previously in the OECD countries

are required, and indeed are already beginning to be implemented in a number of Asian countries. Doubtless, similar challenges will have to be faced by other developing countries outside Asia over the next two to three decades. The recent long-term scenario literature (reviewed in more detail in Grubler, 1998b; and Nakicenovic *et al.*, 2000) indeed reflects such developments. Characteristic projected future global sulfur emission levels range between 20 and 80 Tg S by 2050 and between 15 and 60 Tg S by 2100. The comparatively low levels of projected future sulfur emissions reflects the assumed phase in of sulfur controls also outside the industrialized countries.

Sulfur reduction policies aiming to protect local and regional populations and ecosystems have one interesting side effect: they lower the cooling effect caused by sulfate aerosols in the atmosphere, thus increasing the warming arising from future greenhouse gas emissions (Rogner and Nakicenovic, 1996; Subak *et al.*, 1997) (*see* Aerosols, Effects on the Climate, Volume 1).

NITROGEN

Emissions of nitrogen compounds take many forms and originate from a wide array of different sources, natural and anthropogenic. Because of this diversity, individual source categories are studied in much less detail and therefore large uncertainties prevail.

Nitrogen emissions occur in three principal molecular forms: as nitrogen oxides (NO and NO_2 that are subsumed generally as NO_x), principally formed in high temperature combustion (burning of fossil fuels, or natural lightning); as ammonia (NH_3), principally arising from animal manure; and as nitrous oxide (N_2O), a powerful greenhouse gas, principally arising from soil microbiological process as well as agricultural activities and animal manure. Both NO_x and NH_3 are characterized by short atmospheric residence times and thus by only regional to continental dispersion from their respective emission sources. Their ecological significance arises principally in connection with acidification impacts (although NO_x has also a significant influence on atmospheric chemistry, including ozone (O_3) destruction, and therefore is indirectly affecting GHG concentrations in the atmosphere). Nitrous oxide is a powerful, long-lived (120 years) greenhouse gas whose atmospheric concentrations are estimated to have been 275 parts per billion by volume (ppbv) in pre-industrial times and have been measured at above 310 pbbv in the mid 1990s (IPCC, 1995). For ease of comparability, all emissions are expressed here in elemental weight of nitrogen per year ($Tg\,N\,year^{-1}$).

NO_x has long been of concern in the context of acidic deposition. In the last decade, however, the question of nitrogen over-fertilization of the biosphere has also been raised. See, for example, Munn *et al.* (1999, 468). Possible long-term consequences include the creation of mineral deficiencies in forest soils due to leaching, and a general decrease in biodiversity, particularly in grasslands. Indeed, some ecologists are concerned that nitrogen overfertilization constitutes a long-term threat to the whole boreal forest system.

Until now, most research has focussed on emissions of nitrogen oxides (NO_x, for a review see Smil, 1990), especially for energy-related emissions source categories since motorized traffic is one of the main sources of NO_x emissions and a major contributor to urban smog. Conversely other source categories, including natural processes have been much less studied and large uncertainties prevail. The first nitrogen inventory covering all three gases and all source categories at a regionally highly desegregated level has been developed by Olivier *et al.* (1998), based on earlier studies of Olivier *et al.* (1996), Lee *et al.* (1997); and Bouwman *et al.* (1997), and the discussion here draws heavily on this study. A summary of main emission categories is given in Table 2.

Nitrogen emissions are dominated by anthropogenic sources: 77(37 113) Tg N compared to 42(16 80) Tg N natural sources. In terms of their contributions to total nitrogen emissions, NO_x and NH_3 dominate with 50(22 81) and 54(23 88) Tg N each, compared to 15(8 24) Tg N in the case of nitrous oxide. For anthropogenic emissions, ammonia (43(20 61) Tg N) surpasses NO_x (31(16 46) Tg N), whereas nitrogen-wise, nitrous oxide is a comparatively small source of nitrogen (3(1 6)) (IPCC, 1995 indicates a slightly higher uncertainty range of 4 8 Tg N for nitrous oxide), cf. Olivier *et al.* (1998).

For emissions of nitrogen oxides (NO_x), the dominant anthropogenic source category is the burning of fossil fuels, most notably of automobile fuel and in the generation of electricity. NO_x emission levels depend both on nitrogen content in fuels as well as on very diverse and variable operating and firing characteristics: NO_x emissions tend to increase with increasing burning temperature. In this case, tradeoffs in improving environmental performance become apparent: improving efficiency of energy conversion and lowering of carbon emissions, e.g., in an electric power plant, requires an increase in firing temperatures (the second law of thermodynamics), which tends to increase NO_x emissions. Reducing the latter requires catalytic reduction, which in turn involves an efficiency penalty, slightly increasing fuel use and hence carbon emissions. For cars de-NO_x catalytic equipment also depends critically on operating temperature: at cold engine startup catalytic converters do not function. Therefore related emission estimates of this category of emissions are highly uncertain. Because of the dominance of industrialized countries in global car ownership and electricity consumption, they account for over 75% of global NO_x emissions from road transport and for 70%

Table 2 Global nitrogen emissions as estimates for 1990 per major source category and flux (NO_x, NH_3, and N_2O) and uncertainty ranges (in Tg N year^{-1})

	NO_x (1990)	+/−	NH_3 (1990)	+/−	N_2O (1990)	+/−
Anthropogenic

of all NO_x emissions from fossil fuel burning (Olivier *et al.*, 1998). Anthropogenic NO_x emissions are also the only ones where estimates of long-term historical time series are available. For instance, the estimates of Dignon and Hameed (1989) indicate that global NO_x emissions have increased by almost a factor five over the period 1930 1980.

For ammonia (NH_3), the dominant source of anthropogenic emissions is the agricultural sector, including emissions from animal manure (22(10 30) Tg N) and application of fertilizer (9(4 14) Tg N), that combined account for over 70% of NH_3 emissions globally. The dominance of agricultural sources also explains that contrary to the case of NO_x ammonia emissions predominantly originate in developing countries (a detailed discussion of NO_x, NH_3 and N_2O emissions in India is given by Parashar *et al.*, 1998), which accounted for approximately 70% of agricultural and total ammonia emissions in 1990. Rising animal populations, as well as rising fertilizer use and resulting ammonia (and nitrous oxide, see discussion below) emissions are the other side of the coin of vastly increased agricultural production for ever rising populations (Figure 6). The increase to over 80 Tg N year^{-1} would have been impossible without

the major technological breakthrough of the Haber-Bosch method of ammonia synthesis introduced in 1912.

For emissions of nitrous oxides, the dominant anthropogenic sources are again fertilizer applications and animal husbandry (manure) in the agricultural sector (2(0.3 4.3) Tg N year^{-1} in 1990). The third largest source are industrial processes (production of adipic and nitric acid) with 0.3(0.1 0.5) Tg N estimated for 1990 (Olivier *et al.*, 1998), albeit these emissions are declining rapidly due to implementation of voluntary industry measures due to climate change concerns (Nakicenovic *et al.*, 2000). Yet, even with drastic emission reductions, a long-term legacy of nitrous oxide emissions remains due to its long residence time in the atmosphere. As in the case of ammonia emissions, developing countries, with their high population and food requirements, dominate global emissions, producing about 60% of agricultural and of total nitrous oxide emissions (Olivier *et al.*, 1998). Even though emissions from natural processes, particularly microbiological processes in soils, greatly exceed anthropogenic emissions (3 8 Tg N versus 1 6 Tg N respectively), emissions of nitrous oxide are a good illustration of the impacts of a growing world population and of changing diets (towards higher meat consumption) on NO_x emissions. These in turn require increased food output and changes in agricultural practices and technologies that result in increased emissions, even if the long-term history of ammonia and nitrous oxide emissions remains to be researched.

The literature on long-term nitrogen emissions scenarios is sparse. Due to the multitude of gas species and source categories, no scenarios exist that treat nitrogen emissions comprehensively. The most detailed projections available currently are those developed under the auspices of the IPCC Special Report on Emissions Scenarios (Nakicenovic *et al.*, 2000), but even there, projections for ammonia emissions are lacking as the study focussed on (direct and indirect) greenhouse gases. Nonetheless, the study re ects current best knowledge on uncertainties in future nitrogen emission levels. By 2050, global nitrogen emissions could span a range of 45 110 MtN (N_2O and NO_x) and by 2100 a range of 20 170 MtN (compared to 37.6 MtN excluding NH_3) in 1990 as estimated in Nakicenovic *et al.* (2000). Thus, over the long-term, nitrogen emissions could range between half of current to about four times current levels indicating the large uncertainties in underlying driving forces such as population and economic growth, future developments in the agricultural, energy, and transport sectors as well as in technology.

Because of the multitude of gases and sources, nitrogen emission estimates are poorly understood and uncertain with the paucity in both past and present inventory data and future emission scenarios. More research is therefore needed before considering policy interventions to control these gases beyond well established source categories (e.g., nitrogen oxide emissions from automobiles, or nitrous oxide emissions from adipic acid production). *See* **Nitrogen Cycle**, Volume 2; **Nitrogen Deposition on Forests**, Volume 2.

LINKING EMISSIONS TO DRIVING FORCES: THE CASE OF ENERGY-RELATED CARBON DIOXIDE

Emissions are the result of a large set of interrelated driving variables in the domains of demographics, economics, resources and technology as well as (environmental) policies. Economic, social and technical systems and their interactions are highly complex and this short discussion cannot provide a comprehensive overview.

Instead, the links from demography and the economy to resource use and emissions will be discussed in a simpli ed format using proxy variables for various categories of driving forces. A frequently used analytical approach to describe these linkages is through the so called IPAT identity (Equation 1):

$$\text{Impact} = \text{population} \times \text{af uence} \times \text{technology} \quad (1)$$

where environmental impacts (emissions) are the product of the level of population times the af uence (income per capita) times the level of technology deployed (emissions per unit of income) (*see* **DPSIR (Driving Forces Pressures State Impacts Responses)**, Volume 4). The IPAT identity has been widely used in the analysis of energy related carbon dioxide emissions (for a review see Alcamo *et al.*, 1995; Gaf n, 1998; and Nakicenovic *et al.*, 2000) where it is generally referred to as the KAYA identity (Kaya, 1990) (Equation 2):

$$\begin{aligned}\text{Carbon dioxide emissions} &= \text{population} \\ &\times (\text{GDP/population}) \times (\text{energy/GDP}) \\ &\times (\text{carbon dioxide/energy}) \end{aligned} \quad (2)$$

In this extended IPAT identity, emissions are represented as the product of population times their level of af uence (gross domestic product (GDP)/capita), multiplied with two proxy variables for the level of technology, i.e., the ef ciency of energy use per unit of GDP (Energy/GDP) as well as the carbon intensity of energy used (carbon dioxide/Energy). We classify these latter two variables as proxy variables for technology as they represent highly aggregated indicators that in addition also depend on many other factors, all related to income levels. These include the structure of the economy (e.g., industry versus service orientation), consumption patterns and the extent and nature of environmental policies. Energy price differences also matter, but are generally not related to differences in income levels. Frequently, the poor while unable to afford (high

priced) commercial energy forms such as electricity, rely on traditional fuels gathered largely outside the formal economy. Their costs however can be very high when considering the amount of time spent gathering fuelwood and environmental externalities such as high levels of indoor air pollution associated with burning of traditional fuels in open fire places (Smith, 1993). In turn, with rising incomes, consumer preferences shift to higher priced commercial energy forms (electricity, gas). Cleanliness and convenience of use afford a quality premium (willingness to pay higher prices), including higher energy efficiency and lower emissions (particulates, sulfur, carbon dioxide) per unit of energy. Thus, at the point of final energy use the energy and carbon intensity of the KAYA identity are related to income levels (affluence). This may not necessarily be visible in aggregated data, as the provision of clean energy forms at the point of consumption can entail efficiency losses and proportionately higher emissions at the point of energy production, e.g., when electricity is generated in traditional coal fired power stations.

This multiplicative identity has the advantage that percentage growth rates of its components are additive, thus giving a first approximation of the scale of influence on emissions growth of different driving variables. However, despite the appeal of a simple representation, there are important caveats to bear in mind when using the above identity in interpreting past emissions trends (or future emission scenarios). The first is the issue of spatial heterogeneity. The second one is that it is not possible to treat the growth of individual components independently.

For example, on face value, the KAYA and IPAT identities would suggest that carbon dioxide emissions scale linearly with population; that is, doubling the population means doubling the emissions. However, there are reasons to doubt such a simplified view. There is great heterogeneity among populations with respect to greenhouse gas emissions, so where the population increase takes place is not necessarily the same as where emissions increase. The ratio of *per capita* emissions of the world s richest countries to that of its poorest countries approaches ratios of several hundred (Gaffin, 1998). This problem requires one to consider spatially desegregated population growth. Of course, some level of aggregation is necessary for a global analysis. The biggest correction on emissions takes place when switching from a global to a breakdown of industrialized (IND) versus developing (DEV) countries (Lutz, 1993) (Table 3).

The second caveat relates to the fact that it is not population *per se* that emits carbon dioxide, but the technologies that people employ and the goods and services they consume with their available income. This raises the issue about the relationship between demographics and economic growth (between population and affluence in the IPAT identity) as well as between technology and affluence, which in turn would preclude consideration of a simple linear interpretation of the role of population growth in emissions.

Demographic development interacts in many ways with social and economic development. Fertility and mortality trends depend, amongst other things, on education, income,

social norms and health provisions. In turn, they determine the size and age composition of the population. All factors combined are recognized as important in explaining long-run productivity and economic growth and technological change as well (Barro, 1997). In turn, long-run per capita economic growth is closely linked with advances in knowledge and technological change. In fact, analysis of long-run macroeconomic growth accounts (e.g., Solow, 1956; Denison, 1962, 1985; Maddison, 1995; Barro and Sala-I-Martin, 1995) confirm that advances in knowledge and technology form the single largest source for long-run economic growth, more important than growth in other factors of production like capital and labor. Abramovitz (1993) demonstrates that capital and labor productivity cannot be treated as independent from technological change. In terms of the IPAT identity, it is thus not possible to treat the affluence and technology variables as independent from each other either. In addition, pollution abatement efforts appear to increase with income, a relationship often referred to as the environmental Kuznets curve that seems well established for traditional pollutants such as particulates and sulfur (e.g., World Bank, 1992) but which has not been demonstrated for aggregate greenhouse gas emissions.

Technological, economic and social innovations have long been means by which a greater number of people could live from the same environmental resources. The best known historical examples of major periods of innovation include the Neolithic revolution (beginnings of organized agriculture from around 10 000 years ago); and the Industrial Revolution beginning two centuries ago (Rosenberg and Birsdzell, 1996). In each case, changes in patterns of primary production (food, energy, materials), the efficiency of resources use, as well as changes in environmental impacts have been linked to changes in social organization, institutions, economy and technology (Mumford, 1934; Landes, 1969; Mokyr, 1990). No one of these changes can be considered to be the primary driver, nor as independent from the others: each played a role in an interconnected system.

Before the Neolithic revolution, the world population amounted to perhaps 5 10 million. Over the following millennia complex societies developed based around cities, with highly differentiated social roles and complex political, economic and legal systems. By the birth of the current major religions 1500 2500 years ago, world population had increased to around 300 million. Following a period of cultural, economic and technical stagnation to about 1000 AD with notable exceptions in China and the Islamic world (Mokyr, 1990), further population growth began with the productivity increases resulting from cultural, economic and technological developments associated with the European Renaissance. By the time of Thomas Malthus in the late 18th century, the global population had reached about one billion. The six-fold increase in global population over the following 200 years has been enabled by a continuing revolution in medical, agricultural and industrial technology. However, the most remarkable change in recent decades has been the so-called *demographic transition*, as people increasingly manage their own rate of reproduction, leading to a decline in population growth rates (see Table 3) or to a stabilization of population size in many parts of the world (*see* Population Sizes, Changes, Volume 2; Demographic Change: the Aging Population, Volume 3; Global Population Trends, Volume 3; Urban Population Change, Volume 3; Demographic transition, Volume 5).

This transition has typically been linked to improved education, female empowerment, access to information, improved medical services (and related reductions in infant mortality) and social and economic development facilitated by the international diffusion of new technologies. Therefore, it is not possible to treat changes in demographics, income, and technology as independent from each other.

With the above caveats in mind, let us consider the quantitative evidence since the onset of the Industrial Revolution (ca. 1800), cast in terms of the KAYA identity.

Table 3 summarizes the growth of population, *per capita* income, energy use per unit economic activity and energy related (gross) carbon emissions per unit energy used since 1800. The estimated indicators represent a revised updated data set based on Grubler (1998a); Grubler and Nakicenovic (1994) and Nakicenovic and Grubler (2000). Data with a finer temporal and spatial resolution are available from the author upon request. Because the energy use data include the historically important non-commercial uses of traditional biofuels, the resulting energy use and energy intensities (energy use per unit of GDP) estimates are subject to a high degree of uncertainty; the values given here represent a conservative lower bound estimate and are subject to further research and revision. Total energy use in the 19th century industrialized countries and in developing countries prior to 1975 (see the discussion in Nakicenovic *et al.*, 1998) are thus likely to be underestimated. Resulting historical improvements in energy intensities (including all energy forms) may consequently also be significantly underestimated. For instance the aggregate improvements in energy intensity of 0.5% $year^{-1}$ since 1800 for the industrialized countries (including Eastern Europe and Russia) given in Table 3, need to be contrasted with estimates for individual countries with good historical records that indicate long-term improvement rates of about 1% $year^{-1}$ since the 19th century (Nakicenovic, 1984; Martin, 1988; Grubler, 1991) and much higher rates since the early 1970s (reflected in Table 3). Non-commercial energy use and resulting energy intensity improvement rates for developing countries prior to 1975 are particularly

uncertain, possibly underestimated by up to a factor of three.

In order to simplify, only two macro-regions (industrialized versus developing countries) and trends between five major dates are shown. Interspersed between the main historical dates, the respective annual growth rates of these indicators calculated over their respective time periods are shown in italics. Total period (1800 2000) growth rates are presented in bold (most far right column in Table 3). As mentioned above, the relative magnitude of the growth rates and how they sum up to explain the growth rates in energy related carbon dioxide emissions are indicative only as they do not capture the interdependence among variables; notably between technology and economic growth on the one hand and demographics on the other.

A first observation on Table 3 is that there is no uniform, unambiguous answer about what (proxy) driving force dominates in explaining historical emissions growth. Component growth rates are highly variable across regions and over time. On the positive (i.e., emission increasing) side of the KAYA identity are population growth and increases in *per capita* incomes, on the negative (emission decreasing) side of the identity are improvements in energy intensity (energy use per unit of GDP) as well as decreases in the ratio of (gross) carbon emissions per unit energy used, a trend termed frequently as *decarbonization* (Grubler, 1991; Nakicenovic, 1993).

Demographic and economic development tend to increase emissions, a trend partly compensated by improvements in the two proxy variables representing technology. Globally, an average increase of 1.6% $year^{-1}$ in (gross) energy related carbon emissions since 1800 can be decomposed into roughly equal contributions from population and *per capita* income growth (average 2.1% $year^{-1}$) to be contrasted against an about equal contribution from improvements in technology (energy intensity improvements and decarbonization) of jointly $-0.5\%\,year^{-1}$. However, these numbers vary enormously depending on which time period is being considered, as well as across regions.

As discussed above, the component variables of the KAYA identity are not independent from each other. For instance, the influence of technological change goes far beyond the numbers captured in the percentage rates of change of the energy intensity and decarbonization variables presented in Table 3; this is because technological change is also the main source for productivity growth and hence increases in *per capita* incomes. This illustrates the paradox of technological development (Gray, 1989), where technology is both the source as well as the (partial) remedy of the historical increases in environmental burdens. Prometheus unbound (Landes, 1969) has released the powers of technology that helped humans to expand in numbers at ever higher levels of affluence, thus increasingly burdening the global commons. But technological change has also helped to reduce (part of) these environmental burdens by improved efficiency in the use of energy and the carbon atom. More research is needed to answer the question, if and how fast the paradox of technological development may be resolved in the future, tilting the balance of the equation towards stabilizing emissions, even their long-term decline. The challenge becomes compounded by the inevitable demographic momentum (the mothers of the future are already born today) that makes in increase of global population to some 8 billion almost a certainty (Lutz *et al.*, 1997). There is also a need for continued social and economic development for the larger part of the global population still excluded from the benefits of the use of modern technology.

Anthropogenic Metabolism and Environmental Legacies

PAUL H BRUNNER AND HELMUT RECHBERGER

Vienna University of Technology, Vienna, Austria

For prehistoric Man, the total metabolism (input, output and stock of materials and energy to satisfy all human needs for provisions, housing, transportation, etc.,) was mainly determined by the physiological need for food, for air to breathe, and for shelter. The material turnover of modern Man is 10- 20 times larger. The fraction that is used for food and breathing is small. The so-called anthropogenic metabolism covers not only the physiological metabolism but includes also the thousands of goods and substances necessary to sustain modern life. "Anthropogenic" stands for man-made. The Anthroposphere is the sphere in which human activities take place, sometimes called technosphere or biosphere. Today, the most important man-made material flows are due to activities such as cleaning, transporting, residing and communicating. These activities were of little metabolic significance in prehistoric times.

Even more astonishing than the increase in the material flows is the tremendous material stock, which mankind has been accumulating, and which continues to grow faster than ever. This stock is found everywhere. It begins with mining residues left behind as tailings. It goes on with the material stocks of industry, trade and agriculture, and culminates in the urban stock of private households and of the infrastructure for transport, communication, business and administration. It ends with the comparatively small but growing material wastes in landfills.

The difference in stock accumulation between prehistoric and modern times is striking. Present-day material stocks amount to about 3- 400 tons per urban citizen. We have to manage and maintain this stock. Today's societies have to make far-reaching decisions about the constant renewal of the urban stocks, such as buildings, roads, communication systems, etc. The residence time of materials in the stock ranges up to 100 years. This means that once a material is consolidated into the stock, it will probably not show up quickly in the output of the stock, namely in waste management.

The presence of this large and growing stock has many implications:

1. *as an important reservoir of valuable resources, it holds a tremendous potential for future recycling;*
2. *as a mostly unknown source of materials, the importance of which is not yet in focus, which awaits assessment with respect to its significance as a resource and as a threat to the environment;*
3. *as a long-term source of severe pollutant flows to the environment. An assessment has been made that urban stocks contain more hazardous materials than so-called hazardous waste landfills, which are a focus of environmental protection;*
4. *as a challenge for future planners and engineers to design new urban systems. In the future, the location and amount of materials in city stocks should be known. Materials should be incorporated into the stock in a way which allows easy reuse and environmental control;*
5. *as an economic challenge to maintain high growth rates, building up even larger stocks, and setting aside sufficient resources to maintain this stock properly over long periods of time.*
6. *as a challenge to simulation modelers, who must deal with the complexities of the many processes contributing to urban metabolism, including the influence of long-term global, regional and local environmental, socioeconomic and cultural changes (*see ***Contaminated Lands and Sediments: Chemical Time Bombs?****, Volume 3).*

METABOLISM OF THE ANTHROPOSPHERE

Phenomenology: Growing Stocks and Flows Surpassing those of Nature

The following phenomena are typical for the metabolism of today s affluent societies:

- rates of material consumption and stock accumulation are high and growing;
- for many materials, man-induced material flows exceed natural flows;
- consumption emissions are surpassing production emissions;
- the metabolism of cities is mainly linear (throughput economy), thus cities are heavily dependent on their hinterland as a source for raw materials, as a partner for trade of manufactured goods, and as a sink for dissipation.

High Growth Rates of Material Flows and Stocks in Affluent Societies

As presented in Figure 1 and Table 1, the household consumption of goods has increased from prehistoric to modern times by more than an order of magnitude. The term *good* is used for products with a positive or negative economic value. A good is made from substances, which are defined as chemical elements or compounds consisting of uniform units such as atoms (element) or molecules (compound). The term materials stands for both goods and substances. This growth is even larger if all of the materials used in mining, agriculture, forestry, manufacturing, distribution and consumption are included. The main target of these large material flows is the consumer. With his/her

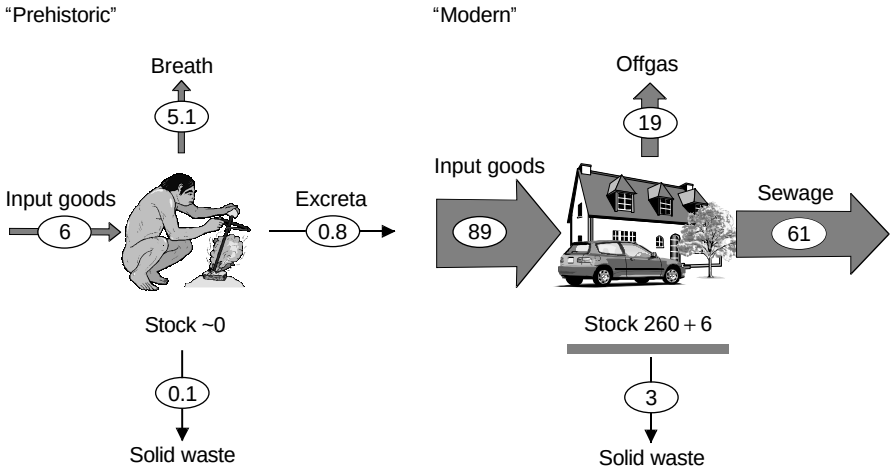

Figure 1 Material turnover of prehistoric and modern Man, in tons per capita per year. Included are all materials used in private households to satisfy the needs for food, shelter, hygiene, transportation, communication, etc., (for details, see Baccini and Brunner, 1991)

Table 1 Comparison of material flows and stocks for selected activities for prehistoric and modern Man[a]. T/c.y stands for tonnes per capita per year

	Material turnover t/c.y		Material stock t/c		Annual change in material stock t/c.y	
Activity	Prehistoric	Modern	Prehistoric	Modern	Prehistoric	Modern
To clean	<0.1	60	0	0.1	0	<0.1
To communicate	0	10	0	160	0	3
To reside	<0.1	10	<0.1	100	0	3
To breathe	4	4	0	0	0	0
To nourish	1.6	1.7	0	<0.1	0	<0.1
Total	6	86	<0.1	260	~0	+6

[a] The most outstanding and unprecedented features of today's economies are the very large stock of materials that have accumulated in the anthroposphere. ''To clean'' comprises water, chemicals and equipment needed for laundry, dishwashing, personal hygiene, toilet etc.; ''to communicate'' takes account of the transport of persons, goods, energy and information due to the needs of private households (including materials for road construction); ''to reside'' consists of the buildings, furniture, appliances etc., needed for living; ''to nourish'' includes all flows of goods associated with the consumption of food within private households, e.g., food, water for cooking, etc.

high purchasing power, he/she is able to pull vigorously at the end of the material chain, buying products larger quantities of consumer goods and energy (Schmidt-Bleek *et al.*, 1996). The terms rucksack and gray characterize the invisible energy, materials and wastes associated with the production of a good during primary production and manufacturing of the constituents and the product itself.

The lifestyle of modern urban Man demands a large amount of materials and energy to sustain his/her metabolism. The reasons are manifold. Economic conditions in the affluent part of the world allow large consumption flows. Resources such as energy and minerals are still abundant and cheap. The early warnings about the limits to growth due to diminishing resources (Meadows *et al.*, 1972) proved to be (numerically, but not in principle!) wrong. Advanced technology enables the development of new products in shorter cycles, making many appliances obsolete before the actual end of their life. Consumption seems to be a value *per se*; many modern consumer products transfer social prestige from the product to the owner. Although there may be small signs of consumer fatigue or even opposition here and there, in general there is no realistic alternative to this growth in material consumption in sight. It remains to be shown that the decoupling of economic progress with the growth of material consumption is economically feasible. It is obvious that developing countries, which still consume at a much lower rate, wish to reach the same material turnover rates as in the most affluent societies.

Compared to the flows of goods, the increase in the flows of many substances, such as lead, is much more dramatic. It has been estimated (Settle and Patterson, 1980) that the mining of lead rose during the last 7000 years from about 1 ton $year^{-1}$ to more than 3 million tons in 1990 (Figure 2). The situation is similar for other metals, and for natural and synthetic organic substances. Due to technological and economic development, there are constant shifts in the use of materials. This is illustrated by the changes in the amounts of materials used for construction in the US (Figure 3). Wood is no longer the key construction material, concrete dominates, and plastic materials are becoming increasingly more important. Metals and organic additives are also growing in importance. In waste management, materials that were used for construction 25 100 years ago, have to be treated now (recycled and disposed of). The nature of these materials will change rapidly in coming decades. There will be more mixtures of more materials reaching waste management sites. The fraction of hazardous waste materials in urban wastes will increase because of the growing consumption of chemicals in the 1970s and 1980s used to stabilize components of manufactured goods. Even if these substances are not used anymore, there exist large reservoirs of banned substances such as chlorofluorocarbons (CFCs) and cadmium (Cd) in the urban stock. As a consequence, waste management must also be capable of handling materials that have not been in use for decades. Prevention is a strategy that has only a slow effect when applied to materials incorporated in the urban stocks with long residence times.

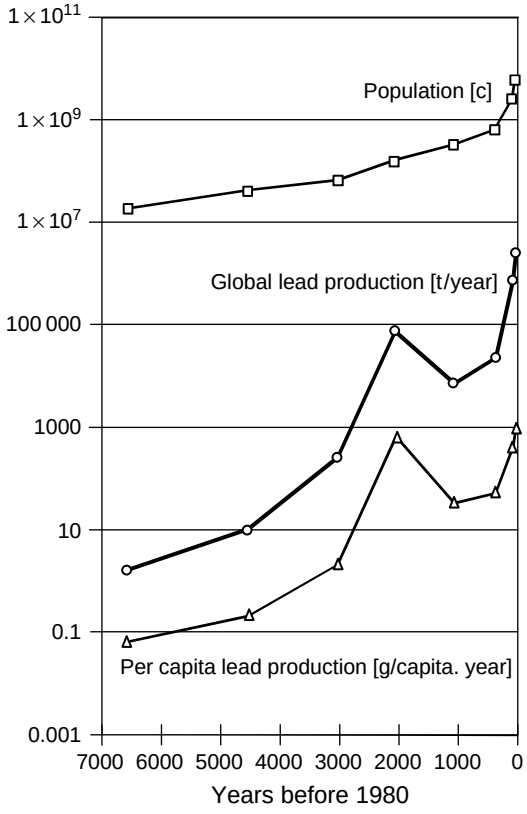

Figure 2 Global production of lead: due to unprecedented progress in mining technology and economic development, the per capita mining of lead increased from 0.1 g $capita^{-1}$ $year^{-1}$ to 1000 g $capita^{-1}$ $year^{-1}$. In combination with the growth of the global population (which increased at a smaller rate than the per capita production), the total amount of lead produced from mining increased from 1 ton $year^{-1}$ to more than 3 million tons $year^{-1}$ (lead data from Settle and Patterson, 1980)

Goods with long residence times are typically incorporated into the infrastructure, such as housing, industry and manufacturing, traffic and communication systems, and so on. A large, and at present mostly unknown mass of substances is stored in this stock. Figure 2 serves as an example. There is little information about today s location of approximately 100 million tons of lead exploited over the last 7000 years. Part of the lead stock is still used as water piping or insulation for telecommunication cables. Another fraction has been dispersed via exhaust gases from cars fueled by leaded gasoline; it remains in the soil and in sediments, and a small fraction has shown up in the Greenland ice caps and other remote areas. Lead has also been land filled with industrial wastes and with municipal solid wastes (MSWs). For the city of Vienna, it has been roughly

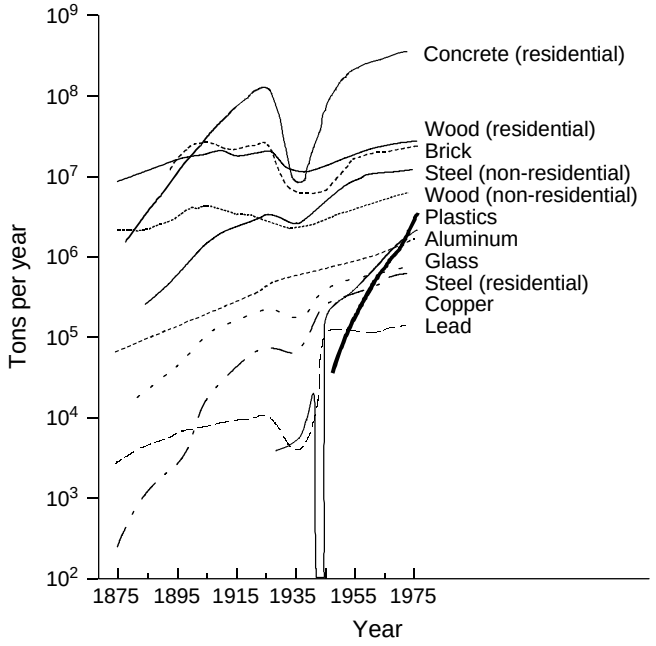

Figure 3 Construction materials used in the US from 1875 to 1975 (adapted from Wilson, 1975). Around 1900, wood was surpassed by concrete as the main construction material. Plastics and aluminum were among the fastest growing construction materials in the 1970s. Change in the consumption of construction materials also alters the construction stock. Future waste management will have to deal with large amounts of plastics and metals such as aluminum and copper

estimated that about 90% of the lead stock is still within the city, either in use or hibernating, and that only 10% is stored in waste landfills (Hendriks *et al.*, 2000). From this point of view, the hazardous substances stored in the so-called hazardous landfills are less than the amounts still within the city anthroposphere. With a few exceptions, the long-term fate and environmental significance of the urban stock of metals and organic materials is unknown (Bergback *et al.*, 1998).

When all stocks associated with the material chain are included, a first assessment reveals the following: waste deposits from primary production (mining wastes such as tailings) comprise about 10% of the total stock; in use and in hibernating materials within the anthroposphere about 80%; and land filled waste products about 10%. Hence, from a mass point of view, the most important future material reservoir is the urban stock, and not landfills and tailings. For an economic evaluation of this stock, the concentrations and speciations of the materials in these stocks may be even more important than the total amounts. The same is true for an environmental assessment. Up to now, the emission rates, chemical species, pathways, and final sinks of substances incorporated in urban stocks have not been investigated in a systematic and comprehensive way. Thus, aside from some specific case studies, it is not yet possible to discuss future effects on the environment, which may occur due to the dissipative material flows from urban stocks.

Anthropogenic Flows Exceed Natural Flows

Due to the large growth rate of the exploitation of essential minerals, man-made flows are approaching and even surpassing the natural flows of many substances. As a consequence, the flows, stocks and concentrations of certain substances such as heavy metals and nutrients are rising, causing the biosphere to change more rapidly and

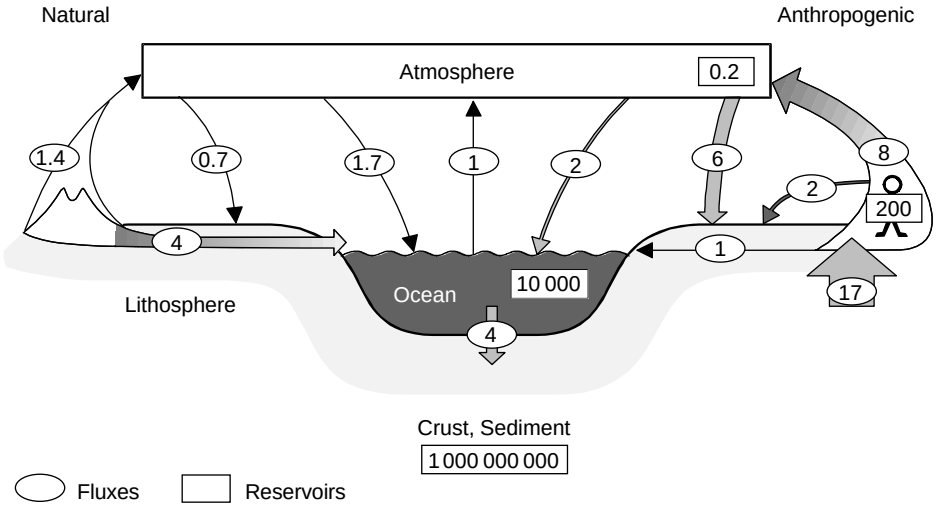

Figure 4 Global anthropogenic and natural Cd flows and stocks in the 1980s, in Kilotons per year (flows), and Kilotons (stocks). The man-made flows surpass the natural flows. Comparatively high atmospheric emissions lead to a significant accumulation of anthropogenic Cd in the soil. The stock of anthropogenic Cd grows by 3% per year. It needs to be managed carefully in the future if long-term environmental impacts are to be avoided (Baccini and Brunner, 1991)

in different directions than without anthropogenic material ows. Cd is used herein as a case study to exemplify the importance of today s man-made ows. In this case there is an abundance of data available. In general, the gap between actual and toxic concentrations in soils is smaller for Cd than for other metals.

In Figure 4, the global natural and anthropogenic ows of Cd during the 1980s are summarized. The total man-made ows of about 17 Kt year^{-1} are more than twice the size of the natural ows of about 6 7 Kt year^{-1} due to erosion, volcanic eruptions, and sea spray. Also, the input into the anthroposphere (17 Kt year^{-1}) is larger than the sum of all outputs (11 Kt year^{-1}) of the anthroposphere. Thus, about 6 Kt year^{-1}, or 30% of the Cd annually mined from the Earth s crust, is accumulated in long-lived goods. The Cd stock in the anthroposphere grows with a rather short doubling time of 30 to 40 years. In the 1980s, the most important pathway for Cd from the anthroposphere to the environment was the atmosphere. This is due to (1) the physical chemical properties of Cd, which has a comparatively high vapor pressure as an element and for most of its compounds; and (2) the lack of appropriate ue gas cleaning technology two decades ago. The man-induced global ows of Cd into the atmosphere were an order of magnitude larger than the natural ows. Today, the emissions into the atmosphere are lower, due to advanced ue gas cleaning technology in metallurgical and waste treatment processes.

The anthropogenic Cd ow by surface waters to the oceans is still smaller than the transport of weathered Cd by the large river systems. The main sink for Cd was and still is the soil, followed by ocean sediments. Regional Cd balances reveal that in densely populated areas, the atmospheric deposition of Cd onto the soil is greater than the output from the soil by leachate, erosion or plant uptake. This situation is indicated in Figure 4 as well. The global input into the soil by atmospheric deposition (6 Kt year^{-1}) and land lling (2 Kt year^{-1}) is much larger than the output by erosion and river systems (1 Kt year^{-1}). Comparing the natural side (ratio of deposition to leaching of 17 : 1) with the anthropogenic side (ratio of deposition to leaching of 8 : 1) in Figure 4, the large accumulation of anthropogenic Cd in the soil becomes evident.

For Cd and other metals, humans are already more important than nature as material transformers. This is true not only at the global level, but also, and more often, at the regional level. Investigations from Sweden (Figure 5) (Bergback, 1992; Azar *et al.*, 1996) show that the weathering rates of several heavy metals are surpassed by the weathering (or emission) rates due to anthropogenic activities.

The consequences for both regional and global levels are the same: the reservoirs in soils, the anthroposphere, and land lls are growing. For some materials, the industrial contribution has already caused the prehistoric concentrations in the reservoir to double, while for others, this will happen in the future, if material management does not change fundamentally. The long residence times of materials in the anthroposphere and, especially in the soil, will result in a long lasting challenge for future generations. Our successors will be given a large source of secondary raw materials, but at the same time they will have to make sure that the emissions from this source are small and under control.

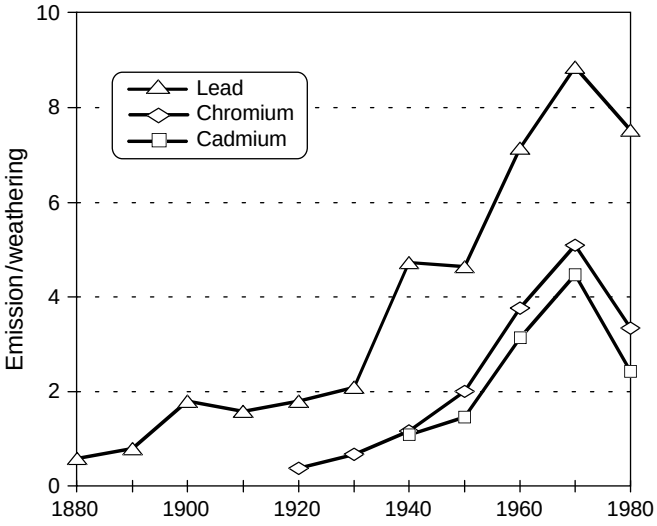

Figure 5 Anthropogenic emission rates of lead, chromium, and cadmium are larger than natural weathering rates (Bergbäck, 1992). Although these examples come from Sweden, similar results have been observed in other countries with advanced economies

Consumption Emissions Surpass Production Emissions

A third phenomenon of the metabolism of advanced societies is that production emissions are decreasing, while certain consumer emissions are increasing. The data (Bergback, 1992) indicate that for heavy metals in Sweden, the change in dominance of industrial sources towards non point sources occurred in the 1970s (Figure 6). This is due to, on the one hand, advanced technology and legislation in the eld of industrial environmental protection. On the other hand, the high and still growing rate of consumption has led to large stocks of materials that have to be maintained and that discharge material that is hardly noticed, but in total is signi cant to water, air, and soil. Hot spots of such non-point sources are cities. Examples of consumer related emission sources are the weathering of surfaces of buildings (zinc, copper, iron, etc.), the emission of carbon dioxide and other greenhouse gases due to space heating and transportation, the corrosion and erosion (chassis, tires, brakes) of vehicles and infrastructure for traf c, and the growing problem of nitrogen overload.

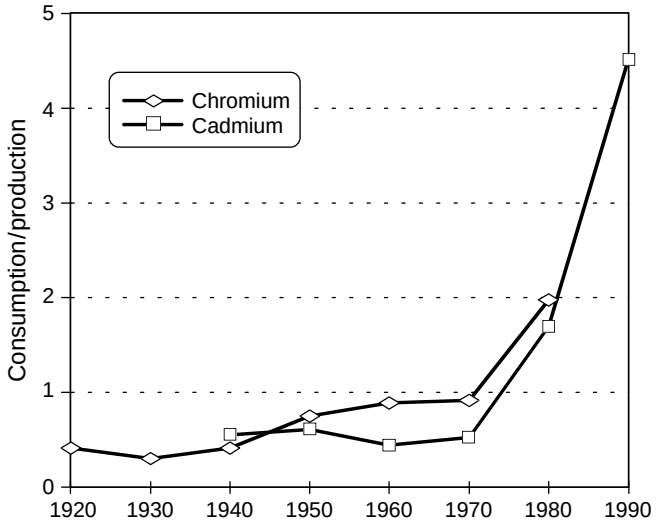

Figure 6 Rates of consumption emissions versus production emissions (Bergbäck, 1992): for modern economies with a high environmental standard, consumption is relatively more important than production. This requires a shift in pollution abatement: future environmental management must concentrate more on non-point sources and on the design of environmentally acceptable products, and has to include consumer behavior and lifestyles

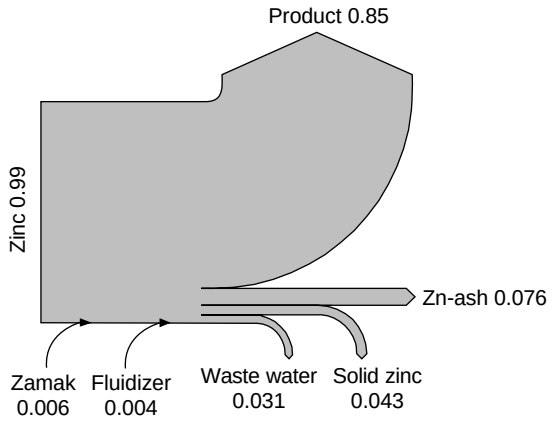

Figure 7 Zinc flow through an advanced electroplating plant: 85% of the zinc used is sold with the product; it protects the product surface against corrosion. Nearly all of the 15% zinc not sold is recycled. Emissions to the environment during production are very small. During use of the zinc-coated product, the major part of the zinc is dispersed in the environment due to corrosion. Hence, despite the effort to protect the environment by pollution prevention measures in the factory, most zinc ends up in the environment

In Figure 7 (Brunner *et al.*, 1996), an example is given to illustrate the significance of consumer emissions versus production emissions. Modern electroplating plants produce only small residues; most of the metals used to protect surfaces leave the factory incorporated in the product. In general, the solid and liquid metal residues are recycled to a large extent, resulting in low losses of metals to the environment. Thus, from a company point of view, the goal of pollution prevention has been achieved, and most of the zinc or chromium leaves the factory as coatings on products. Nevertheless, during the lifetime of the product, processes such as corrosion and weathering damage the surface coating, resulting in losses of heavy metals to the environment. Hence, despite pollution prevention measures during the electroplating process, as much as 85% of the zinc may end up in the environment (Figure 7). Since the corrosion process is slow and the residence time of metals on surfaces can be rather long, the flows of metals to the environment last for years to decades. The legacies of today's protected surfaces are tomorrow's environmental loadings. At present, the significance of such emissions has not been assessed and evaluated. There are no methods available yet to measure and appraise these sources of pollutants to the environment.

To prevent consumer-related emissions is more difficult than to stop industrial pollution: (1) it is a much more demanding challenge for a company to change or discontinue a product than to add an air pollution device to its production facility; (2) the number of (consumer) sources is many orders of magnitude larger than of production facilities; (3) the individual emission may be very small, and only the multiplication by the large number of sources may cause a hazard for the environment. Thus, consumer awareness for the overall relevance of his/her small contribution must be created first, in order to be able to tackle the problem. (4) In general, emissions of industrial sources can be reduced with a much higher efficiency than small-scale household emissions. An example is waste combustion: due to sophisticated air pollution control systems, the specific emissions per tons of waste incinerated has decreased in the last 50 years by several orders of magnitude (reduction of e.g., dust $>10^5$; lead $>10^5$; dioxin $>10^3$). Attempts to decrease emissions by changing consumer behavior (collection of potentially hazardous materials such as lead or chlorinated materials) are not as effective. They reduce the flows by a maximum of one order of magnitude only. So far, the general public does not notice the large cumulative power of consumer emissions. It has not been anticipated yet that the poor practice of burning waste materials in a few home heating systems and wood stoves leads to higher overall loads of dioxins than nationwide state-of-the-art waste incinerators.

The Linear Metabolism of Cities and Their Hinterlands

Today's cities are mainly linear throughput reactors. The material inputs into cities are slightly larger than the outputs, resulting in a growing stock of materials. In Figure 8, the anthropogenic metabolism of Vienna is presented as a

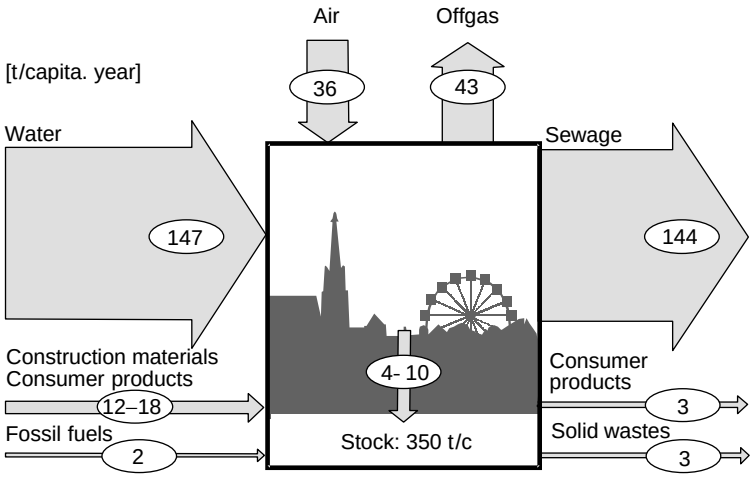

Figure 8 The flows and stocks of materials in the city of Vienna. Inputs (200 t c^{-1} year^{-1}) of materials into the city are larger than outputs, resulting in continuous growth of the already large stock, which doubles in 50 to 100 years. Basically, the modern anthropogenic metabolism can be characterized as a linear throughput reactor, with less than 1% of materials being involved in regional cycles

typical example (Obernosterer *et al.*, 1998). The material stocks in private households, the public and private sectors, and the infrastructure double in about 50 to 100 years. This stock is made up from materials exploited from a local, regional and global hinterland. The hinterland of a city is not a speci c geographical area, but it comprises many scales, depending on the materials discussed. In the case of Vienna, the ow of water, which comprises the largest single ow of a material for all current cities, comes from regional mountain springs, while most construction materials are drawn from local resources. For many metals and nutrients, Vienna depends on a global hinterland. Even if some of the essential materials could still be found locally, it is often more economical to bring in these materials from a globalized world market. Rees calls the impact a city has on the hinterland the *ecological footprint* (Rees, 2001). This footprint comprises materials included in the production of goods, such as water needed to grow food produced in the hinterland but consumed within the city (*see* **Ecological Footprint**, Volume 3).

The large and growing stock of materials in cities represents a resource for the future, if certain conditions are met: the materials must be incorporated into the structure of a city in a way which allows one to nd, collect and separate valuable substances again. The concentrations of the substances must be high enough for economic recovery, or low enough for environmentally safe disposal. At present, this is not the case for most materials. Exceptions are extremely valuable substances such as gold, or highly toxic materials such as plutonium, both of which are managed very carefully. The elevated concentrations of these materials in their nal sinks (soils and sediments) show how dif cult it is to control the ows of materials.

The linear ow through cities means that the hinterland has to cope with the leftovers of urban activities. Hence, the hinterland serves as a supply system for the city on the one hand, but is also a disposal system on the other hand. Actually, the second function is becoming increasingly important. The growth in material ows implies more wastes as well. Due to the build-up of long-term stocks, there is a time lag between material input and output. Future amounts of waste materials will be much larger than nowadays, even if consumption were to remain at present rates. Hence, the city s metabolism and corresponding stock determines tomorrow s emissions and state of the environment in the hinterland!

The importance of the hinterland depends on the waste management system of a city, and the substances involved. For nutrients such as nitrogen, the receiving waters of the hinterland are crucial. While many anthropogenic nitrogen emissions such as NO_x from automobiles or industrial sources can be reduced, the direct nitrogen ows from humans cannot be changed signi cantly; they can only be decreased by expensive wastewater management and treatment methods. Thus, the fast growth of large urban populations can have a severe impact on the receiving water system. In addition, the lifestyle of the urban population is important: if the nitrogen is consumed as animal protein, the hinterland emissions for the production of this protein are very high. If the dietary nitrogen stems from plant sources, the hinterland emissions will be 50% smaller. Thus, in order to protect surface waters as well as adjacent groundwaters, and the estuaries where the rivers join the sea, nutrient management programs on a large scale are necessary, integrating agriculture as the primary source with food industry emissions, traf c emissions and other urban nutrient ows.

While nutrient flows are of concern on a watershed (regional to continental) level, greenhouse gas emissions are of global significance. For every city, the most important hinterland, from a disposal point of view, is the global atmosphere. Without this large conveyor belt and intermediate sink for carbon dioxide, the energy metabolism of cities could not survive a single day! It is the stock of materials in the infrastructure of a city that determines the emissions of greenhouse gases. If this stock includes advanced insulation of residential and commercial buildings, city-wide central heating systems, efficient public transportation, appropriate structures to shorten transportation distances for commuting, shopping and leisure etc., the emissions could be much less than in present cities. Since the residence time of the city stock is long (decades to centuries), a rapid change of materials and structure of the stock is not feasible. Thus, the present stock of materials will determine future emissions of greenhouse gases for quite some while.

Besides the large global and regional emission pathways, there are local sinks for urban wastes, such as landfills. Today, most of the minerals imported into cities are disposed of in sanitary landfills. Although these anthropogenic sediments currently contain not more than about 10% of the stock of metals within a city, they will grow and may become an important source of resources in the future. In particular, if specific wastes are concentrated and accumulated for future reuse and are not diluted with other wastes or additives such as cement, future amounts may become large enough to make re-use economically feasible.

Analysis: How to Assess Material Flows and Stocks?

First attempts to determine the metabolism of urban regions date back to the 1970s. Duvigneaud and Denayeyer-De Smet compared the city of Brussels with a natural ecosystem, and concluded that the knowledge about the material and energy turnover of cities was still very small (Duvigneaud and Denayeyer-De Smet, 1975). They suggested redesigning the city metabolism in a way that allows more recycling, less pollution and better use of resources. Newcombe *et al.*, describe the metabolism of Hong Kong in a similar way. They, too, ask for a better understanding of the key metabolic processes in order to improve future urban design (Newcombe *et al.*, 1978). A comprehensive method to describe the metabolism of anthropogenic systems was developed in the 1980s, and is described by Baccini and Brunner: *material ow analysis* (MFA) is based on the following definitions (Baccini and Brunner, 1991; Brunner *et al.*, 1994): the term *material* stands for both substances and goods. A *substance* consists of uniform units (atoms or molecules) and is a chemical element (e.g., lead, carbon) or a chemical compound (lead chloride, carbon dioxide). Substance flows are measured in mass per time units, substance fluxes in mass per time, and cross section. The cross section can be an entire region, a household, or a person; hence the flux unit might be kg *per capita* and year. The selection of substances for an MFA is a demanding task. In general, for several reasons (data availability, limited resources) the number of investigated substances is small. Therefore, it is necessary to select certain so-called indicator substances. These are elements or compounds that show a behavior typical for a group of substances. For instance, the partitioning of Cd in a combustion process can be regarded as exemplary for volatile elements such as zinc, antimony, and tin. Iron serves as an indicator for nonvolatile metals such as cobalt, chromium, manganese, and nickel. The selection of appropriate indicator elements also depends on the goods and products investigated. Regarding the combustion of coal, for example, arsenic and selenium are appropriate indicators because coal is a major source for these elements (Greenberg *et al.*, 1978). One way to determine indicator elements is to establish the ratio of elemental concentrations in the product to the average in the earth s crust. Elements with high ratios are candidates for the MFA (cf. Table 2). Another criterion for the selection of substances can be emission limits as defined by environmental legislation.

As stated above, a *good* consists of one or many substances, such as a pipe made of lead, or gasoline containing benzene. A good has a negative (e.g., waste) or positive (e.g., car, drinking water) economic value. In the economic sense, goods can also be energy, information, or services. In classic MFA, which is the subject of this article, the term is applied to material goods only.

A *process* is defined as a transport, transformation, or storage (stock) of goods, materials, energy, and information.

Table 2 Ratio of elemental concentrations of oil, coal and MSW (Municipal Solid Wastes) to the average on the earth's crust as a means of selecting indicator elements for an MFA[a]

	Cl	As	Cd	Co	Cr	Cu	Hg	Ni	Pb	Se	V	Zn
Oil/ØEC	*0.7*	*0.4*	0.05	0.04	0.01	0.06	*0.3*	*0.7*	0.02	**10**	**1.5**	0.05
Coal/ØEC	*7.7*	**13**	2.5	0.4	0.2	0.6	*5*	0.4	1.5	**38**	0.3	0.7
MSW/ØEC	**77**	2	**50**	0.2	2	*11*	**100**	1	**62**	6.3	0.03	*17*

[a] Bold figures indicate high relevance, italic figures medium. (Fiedler and Rösler, 1993; Merian, 1984; Tauber, 1988; Zimmermann *et al.*, 1996; Frischknecht *et al.*, 1995).

A transformation often involves a change in the value of a good. There are processes possible on all levels: a car engine may be looked at as a process in the same way as the human body, a private household, a waste incinerator, a branch of a regional economy, or an entire region.

Finally the investigated system comprises the processes that are linked via flows of materials and goods. The system boundary is defined in space and in time. Depending on the objective of the MFA and the availability of data, the boundary in time can be hours, days, or a year.

An *activity* is defined as a set of processes and fluxes of goods, materials, energy, and information serving an essential basic human purpose, such as to nourish, to clean, to reside, or to communicate. Hence, the concept of activities allows one to evaluate the design and management of entire material flow and stock systems with the objective of meeting certain goals such as sustainability. For example, the activity to nourish, comprising the production, upgrading, storage, distribution, preparation, and consumption of food, involves large fluxes of energy, nitrogen and phosphorus, which have an impact on water, air, and soil. An MFA of the entire activity to nourish, including agricultural production, industrial processing, distribution of food, and preparation and consumption of meals reveals those processes and flows of goods which are most important from the point of view of resource conservation and environmental loadings. Thus, MFA is an essential tool for the analysis and design of sustainable systems.

Each flow or flux has a process of origin and a process of destination, and thus is precisely defined. Equally, each process is linked with other processes by means of fluxes or flows. A good, which flows from Process A to Process B (Good 3) is called an output good for Process A and an input good for Process B. Import (Good 1) and export (Good 2) goods are defined as goods which cross the systems boundary. The same terminology applies to the flux of substances. In Figure 9, a process is graphically presented by a square, a good by an oval, and fluxes of goods or materials by arrows. Although these definitions seem tedious, they become important as soon as one attempts to link various data about the flux of materials of individual processes. Often the measurement of the output good X does not yield the same result as the measurement of X as an input good into the next process. For example, the figure for consumption of drinking water varies by 20 30% depending on whether it is measured at the water supply (output good) or the consumer (input good). Daxbeck & Brunner (1993) subdivide an MFA into the following nine steps.

1. Outline of the objectives of the MFA.
2. Definition of the system, including the selection of system boundaries (space and time), processes, goods and substances. First rough assessment of balances of goods and substances, using easily available data in order to identify the relevant goods and processes.

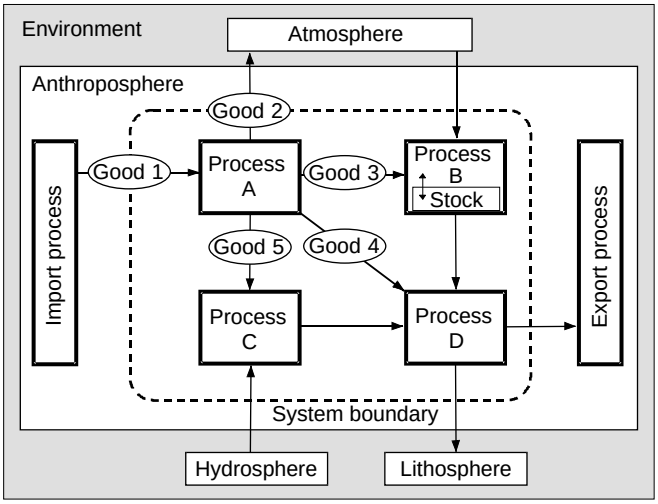

Figure 9 Example of definitions and symbols for system boundaries, processes, and flows of goods as used in MFA methodology

3. Establishing a program for the investigation and measurement of flows of goods and substances, taking into account the necessary accuracy of the final results.
4. Determination of the mass-flows of the goods (m). Mass balance for goods for process A in Figure 9:

$$\sum_{i=1}^{1} m_i = \sum_{i=2}^{5} m_i$$

5. Determination of concentrations (c_j) of the selected substances (j) in the goods.
6. Calculation of the substance flows ($m \times c_j$) including an estimation of the uncertainty of the results. Substance balance for process A in Figure 9:

$$\sum_{i=1}^{1} c_{i,j} \times m_i = \sum_{i=2}^{5} c_{i,j} \times m_i = X_{A,j}$$

7. calculation and optimization of the transfer coefficients (k_j): transfer coefficient of substance j for good 3 of process A in Figure 9:

$$k_{A,3,j} = \frac{c_{3,j} \times m_3}{X_{A,j}}$$

8. popular presentation of the results and interpretations including a detailed report to ensure transparency and reproducibility.

Evaluation: How to Determine the Environmental Significance of the Flows and Stocks?

The results of an MFA are mass balances for goods and several substances. Obviously they can be interpreted separately, as they indicate the most important processes and

goods from which appropriate strategies for an optimized materials management can be derived. In this section, some additional, more or less established, methods for evaluation are briefly described. Initially, these methods were not developed for the urban metabolism, and with the exception of the second approach they have not been applied to the metabolism of cities either. This might be partly due to the lack of data availability, and the practicability and complexity of the methods.

Evaluation by Emission Limits

A rst way to evaluate a material-balance of a system is to compare substance concentrations in various mass- ows with emission standards of related legislation. Usually such limits are laid down for gaseous and aqueous emissions in the various national environmental protection directives. For instance, emissions of factories, power plants, waste treatment facilities and so on, are controlled this way by local authorities. However, non-point (dissipative) emissions and emissions via products and goods can hardly be evaluated by this approach. Therefore, estimates of emissions exclusively by concentrations are not yet suf cient; the total loads discharged into the environment have to be considered as well. The advantage of a complete balance is that the ows of a substance via residues and products that are not regulated by legislation are also evaluated. Nowadays, this aspect is becoming more and more important. For example, as most of today s applied waste treatment technologies obey stringent emission limits, their emissions are negligible and no longer important for decision-making. Nonetheless, due to different process technology, they produce completely different amounts and qualities of residues. A comparison based exclusively on emissions would yield no difference between such technologies, and is therefore not suf cient and is not goal-oriented.

Evaluation by Relating Anthropogenic to Natural Flows and Stocks

This approach investigates the changes of natural ows and stocks through anthropogenic activities (ows and stocks, induced by society). Accordingly, this approach considers the following two important requirements for sustainability (Enquete-Kommission, 1994; SUSTAIN, 1994). First, substance ows from the anthroposphere to the environment should neither exceed local and global assimilation capacity nor surpass the range of natural substance ows. Second, substance ows should be managed in a way to prevent the depletion of useful (resources) substances and the accumulation of harmful substances in the environment. These goals re ect the *precautionary principle* as laid down in modern environmental legislation (*see* **Precautionary Principle**, Volume 4). The principle is derived from the realization that controlling the urban metabolism exclusively via threshold values is not yet possible. First, these values continuously change as a result of enhanced knowledge, and second, they are mostly a result of damage to human health and the environment that has already happened.

The following example demonstrates how the method can be applied. The change in soil by the emission of Cd from a MSW incinerator (anthropogenic-induced material ow) is investigated. The plant processes 200 000 tons of MSW year^{-1}. It is equipped with an advanced ue gas treatment system, which results in an extremely low transfer coef cient of Cd into the off-gas: $k = 0.001$ ($\approx$0.002 mg Cd Nm^{-3}). The mean concentration of Cd in MSW is about 10 mg kg^{-1}. This yields an annual emission of 2 kg Cd to the atmosphere. The plant is situated in an urban area with a population density of 4000 inhabitants km^{-2}. Waste generation rate amounts to about 150 kg per person and year. Thus, the incinerator has a catchment area of roughly 300 km^2. Assuming that the 2 kg of Cd are evenly distributed over this area, a deposition rate of about 7 μg m^{-2} year^{-1} can be calculated. (Actually, due to the aerosol character of the Cd emission, the burdened area would be much larger, and the real deposition essentially lower.) The content of Cd in natural soil is about 70 mg m^{-2}. Therefore, the incinerator would cause a doubling of the Cd content within 10 000 years. Even considering the above simpli cations, such an emission can be judged as environmentally compatible with this approach.

Contrary to the evaluation via emission limits, this approach considers the load of an emission or product. It has been successfully applied to the metabolism of a city by Paumann *et al.* (1997).

Entropy-based Evaluation (MASTER)

MASTER (Method for the Analysis of the Substance concentrations of Treatment End-products and Recycling goods) was initially developed as an evaluation tool for waste management.

The MASTER approach quanti es the power of a system, be it an engine, a factory, or a city, to dilute or concentrate substances with a single measure (Rechberger, 1999). This method can be directly applied to the results of any MFA. While the basis of an MFA is the principle of the conservation of mass (a special case of the First Law of Thermodynamics), MASTER is based on the Second Law (known also as the Entropy Law): the approach utilizes Statistical Entropy to evaluate substance partitioning of a system. It can be expected that entropy is one of several appropriate measures to judge urban metabolism, as it quanti es the dissipation caused by point and non-point emissions as well as of stocks. The advantage of linking MFA and MASTER is that one single measure in the range between [0, 1] per substance and system is derived. Therefore, this coupling is well suited to establish time series for urban material balances.

Life Cycle Assessment (LCA) and Swiss Eco-Points (SEP)

LCA (SETAC, 1996) and SEP (BUWAL, 1998) are methods for evaluating the emissions caused by a product, a process or a system. An LCA consists of the following steps: classification, characterization, and evaluation. First, emissions are identified, inventoried and assigned to predefined stressor categories such as greenhouse effect, ozone depletion, human toxicity, etc., (classification). Second, the contributions of the different emissions are assessed, calibrated and aggregated into relatively homogenous categories (characterization). In the evaluation step, which is optional and not entirely based on scientific principles, but on socio-political (subjective) values, the impacts are weighted and aggregated to one final single index. The SEP method is a one-step process based on the concept of limited environmental absorption capacity for pollutants. Therefore, it uses a weighting system to aggregate substance flows (eco-points) by considering critical loads and actual total loads of selected substances mostly at the national level.

Material Input per Service Unit (MIPS)

MIPS (Schmidt-Bleek, 1994; Schmidt-Bleek *et al.*, 1998) is a measure for the aggregated mass flow due to the consumption of a defined service (e.g., the total material and energy used to transport a good from A to B). In the MIPS concept, all materials including ores, mining wastes, auxiliary goods, water, air, off-gas, etc., which are required to render a certain service, are taken into account for the entire lifetime of the goods associated with the service. The MIPS method defines the procedures to set system boundaries, to generate data and determine how to handle the issue of lack of data. The method is limited to the level of goods and does not allow one to evaluate the substance flows needed for services. It serves well as a method for a first assessment of different options. However, without considering individual substances, the MIPS concept can result in misleading conclusions.

Sustainable Process Index (SPI)

The SPI (Krotscheck, 1995) is based on the assumption that for sustainability, solar *exergy* (available solar energy) is the limiting factor. The utilization and conversion of solar energy into usable exergy by photovoltaic cells, biomass or other means requires a land area. Hence, in an SPI-evaluation, all material and energy flows of the investigated product (or process or system) are transformed by a defined procedure into land area equivalents. The SPI equals the total area calculated for the product, divided by the specific area available for an average person living in the investigated region. Sustainability is achieved if the SPI is <1. The SPI is a so-called holistic approach as it considers not only traditional resources (materials, energy, area) but also attempts to include social aspects such as employment, residential area of employees, etc.

The methods summarized above do not yet allow one to comprehensively evaluate the environmental relevance of the anthropogenic metabolisms. So far, no method exists to appraise the diffusive emissions resulting from the weathering of surfaces in a city, surfaces exposed to the atmosphere (roofs, cars), or buried in the ground (pipes, cables). Also, the long-term fate of materials hibernating in cities has not yet been investigated. Thus, new methods have to be developed in order to supplement existing evaluation methodologies.

Case Studies

The following two case studies illustrate how material flow and stock analysis can be used to assess, evaluate and control the anthropogenic metabolism. Both examples have been developed and used to support decisions in the field of environmental and waste management. They are presented here to point out the qualitative and quantitative importance of material stocks. Efficient decisions regarding environmental protection and resource conservation can be taken only if all flows and stocks of a material and their contributions to the total metabolism are known.

Plastic Materials

The flows and stocks of plastic materials in Austria have been investigated by an MFA (Fehringer and Brunner, 1997). This assessment is summarized in Figure 10. The total per capita consumption of plastics amounts to about 140 kg (8.1 million inhabitants); 50 kg are incorporated into the stock, and 90 kg are collected and treated by waste management systems; 84% of the plastic wastes are land filled, 10% are incinerated, and 6% are recycled. There are two important plastic stocks: the accumulation in the consumption process (buildings, transportation and communication systems, households, industry and trade, etc.), and the waste plastic deposits in landfills. Landfills contain more plastic and grow faster than any other stock.

In addition to polymers such as polyethylene or polyvinylchloride, plastic goods contain additives such as softeners, stabilizers, biocides and fire retardants (Table 3). These additives are much less abundant in packaging materials. The stock of some of the potentially hazardous additives in use and hibernating in Austria amounts to several 10 000 tons. The mass of additives in landfills is even larger. Information on the chemical composition of the plastic flows and stocks is scarce and hard to collect. Hence, an important base for environmental and resource management is lacking at present.

An evaluation of the plastic flows and stocks in view of the goals of the Austrian Waste Management Act (protection of mankind and the environment, conservation of resources materials, energy and space) reveals

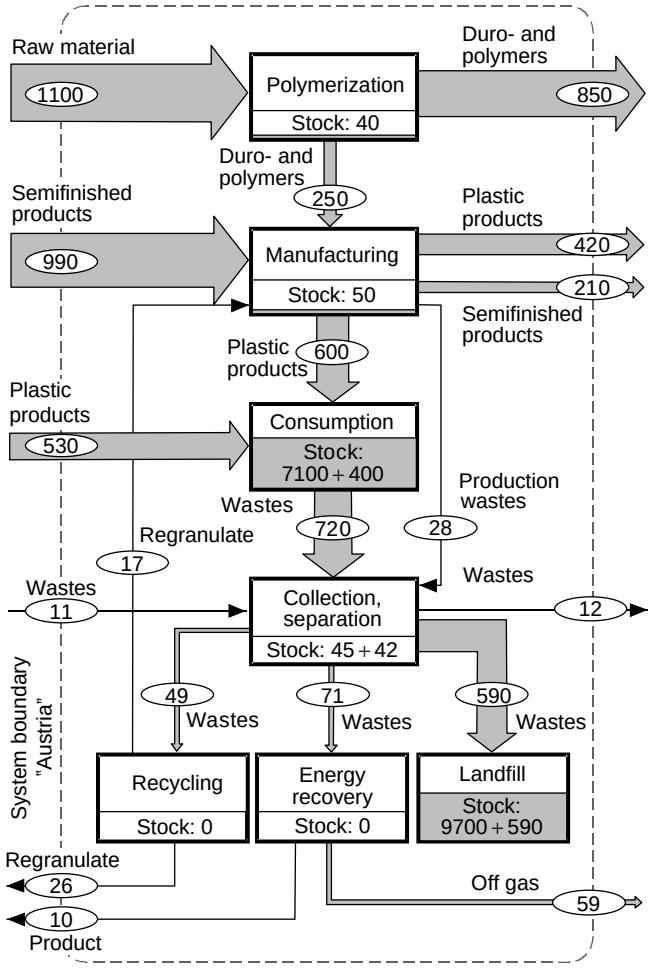

Figure 10 Flows and stocks of plastic materials in Austria in 1994 in kt/year: 40% of the annual consumption of plastic materials is accumulated in the stock. Most of the residual 60% is disposed of in landfills, which are already the largest and fastest growing stocks of plastics in Austria. The federal packaging ordinance, which requires separate collection and recovery of plastic packaging materials, has little effect (<10%) on the overall plastic flows and stocks (Fehringer and Brunner, 1996)

the following. There are hardly any immediate and direct environmental hazards resulting from present plastic waste management. Nevertheless, since the fate of in excess of 10 000 tons of heavy metals and organic substances contained in land filled waste plastic is not known, a long-term risk may exist. This risk needs to be addressed, taking into account slow biogeochemical reactions of polymers and additives, as well as immobilization and mobilization reactions in landfill environments. It must be pointed out that most of today s landfill research is directed towards comparatively fast reactions, which take place within months to years, rarely decades. In the case of polymers, investigations are needed concerning slow reactions, which take place over decades to centuries. First assessments of the behavior of landfill liners indicate that plastic materials are not as stable in landfill environments as anticipated.

Land filling plastic wastes means burying valuable fuel. In Austria, about 500 000 tons of fuel oil equivalents are disposed of in landfills every year. This clearly contradicts the goal of conservation of resources of the Waste Management Act. On the other hand, about 50 000 tons of packaging plastics are recycled at extremely high cost. Recycling of stabilized plastic wastes means keeping the hazardous constituents within the anthroposphere. This cycle either needs to end in an advanced waste treatment plant, where the hazardous materials are extracted, concentrated and immobilized, or the cycle must be improved by new, sophisticated technologies not available yet. In order to integrate products made from plastic wastes, such as artificial wood fences, roof tiles or concrete artifacts in an environmentally sound waste management strategy, concepts for the safe final disposal of these products must be developed as well. Otherwise, the hazardous constituents are dispersed in the environment by burning the artificial wood in household furnaces, etc. The general public cannot be blamed for such practices, since the origin and legacy of recycling products is neither known nor trackable.

Table 3 Characterization of the plastic flows and stocks in Austria. Packaging polymers contain few additives. In contrast, plastic materials with long residence times, e.g., for construction purposes, have to be protected against degradation by light, temperature, mechanical, chemical and biochemical stress. Hence, they often contain large amounts of heavy metals and organic stabilizers. These constituents may jeopardize future recycling. If not properly managed, they will also pollute the environment (data from Fehringer and Brunner, 1996)

Material	Consumption kt 1994	Packaging material kt 1994	Stock kt 1994
Polymers	1100	200	7100
Softeners	14	0.2	140
Ba/Cd-stablizers	0.27	0.0002	2.6
Pb-stablizers	1.8	0.002	18
Fire retardants	2.3	0	22

In the future, decisions regarding the management of plastic materials and wastes should be based on appropriate, comprehensive information, including gures about individual polymers, additives, stabilizers and so on. In order to control the risks and exploit the resource potential arising from large stocks and ows of plastic materials, the management of plastic goods needs to be redesigned. Most polymers are produced from fossil fuels. The largest part of fossil fuels is used for traf c systems, heating, power generation and industrial purposes; plastic manufacturing is of minor importance. The incineration of waste plastics can reduce the overall consumption of fossil fuels and of greenhouse gas emissions. Incineration is especially important for polluted plastic materials, containing hazardous constituents. It is essential that appropriate nal sinks be found for these constituents, such as an ef cient thermal process for organic substances, or a secure land ll for immobilized heavy metals in incineration residues. Recycling cannot solve these problems, unless new technologies are developed to extract the hazardous components from waste plastic mixes. Packaging ordinances cover only a small part of the total ows and stocks of plastics, are inef cient and do not tackle the problem of the hazardous constituents (cf. Table 3). In general, the total pathway and stocks of plastic materials should be taken into account when new plastic goods and management schemes are developed. It may be advantageous to start a new plastic era, where additives are omitted for environmental and recycling bene ts, and where clever chemists nd new polymers with better functions with less heavy metals and hazardous organic compounds.

CFCs

CFCs are a group of highly volatile compounds that contribute to the degradation of the stratospheric ozone layer. They have been widely used in aerosol sprays, in re extinguishing systems, as foaming agents in insulation materials for construction and refrigeration, as cooling agents, and as solvents and cleaning chemicals. In 1987, most CFCs were banned by the Montreal Protocol, due to their stratospheric ozone depletion properties. This treaty had an immediate effect on the consumption of CFCs, and on the emissions of short-term applications such as aerosol sprays. However, the in uence on the stocks of existing CFCs in use and hibernating is long-term. Waste management will have to deal with large amounts of CFCs during the coming decades, and recovery of the ozone layer will be a slow process.

In order to evaluate environmental and waste management strategies in the eld of CFCs, the ows and stocks of these chemicals were comprehensively investigated in a case study for Austria (Obernosterer, 1994). In Figure 11, the results of an MFA are summarized in ozone depletion units (ODP); these units are applied to account for the different effects of individual CFCs on the stratospheric ozone layer. The largest stock consists of insulation materials in construction. Other foams, coolants and re extinguishing agents account for about half of the CFC stock, household refrigerators for less than 3%. The OPD units in the present stock account for about one-third of all CFCs ever used in Austria. Thus, if not properly disposed of, the degradation of the ozone layer by CFCs will continue.

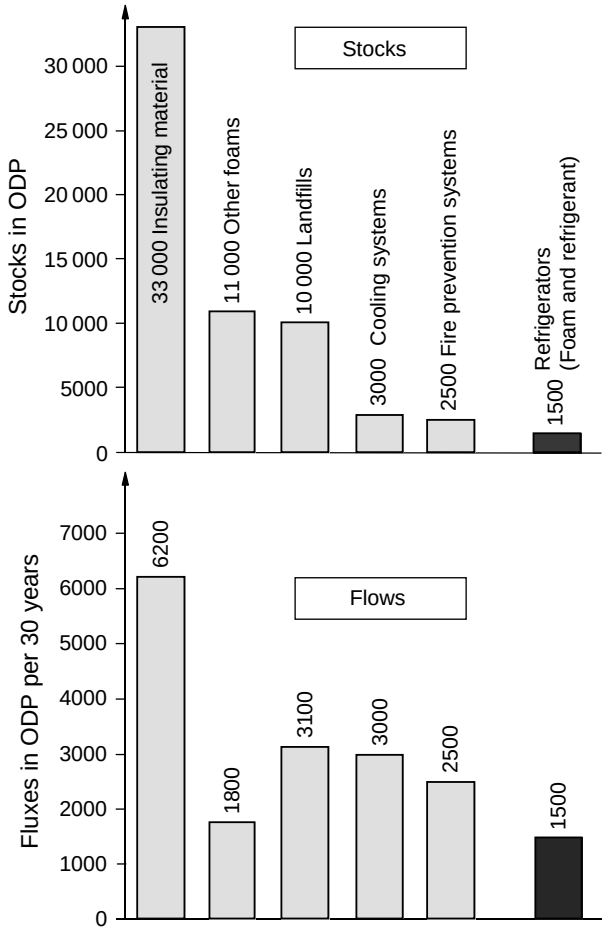

Figure 11 CFC stocks and emissions in Austria over the next 30 years, expressed as ODP. The largest stock and emission is due to insulation materials for construction. At present, waste management regulation focuses mainly on refrigerators, but this comprises less than 10% of the entire CFC stock and emissions in Austria (Obernosterer and Brunner, 1997)

The largest ow (emission) over the next 30 years will come from the stock of insulation materials in buildings. MFA reveals that top priority should be given to the ef cient collection and disposal of construction wastes. At present, legislation in the eld of waste management focuses mainly on refrigerators, which account for less than 10% of the emissions.

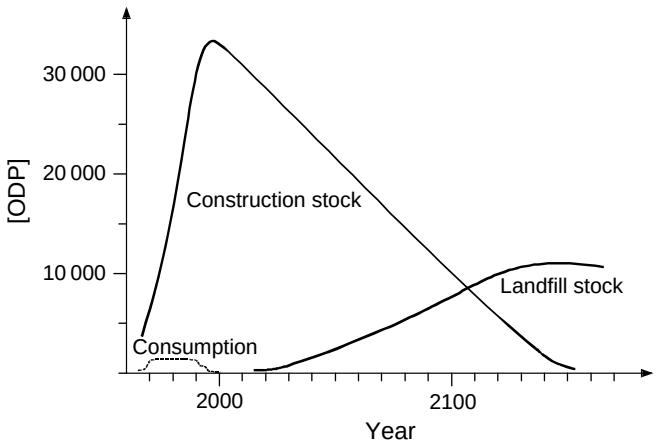

Figure 12 Consumption, buildup and shift of stocks of construction-related CFCs. During a relatively short consumption period of 25 years, a large stock of CFCs in insulation materials has accumulated, which will have to be managed carefully for the next 100 years. According to present waste management practice, this stock will be shifted gradually to landfills. If no counter measures are taken, CFCs will be lost to the stratosphere from both stocks – construction and landfills

The case studies of plastics and CFCs represent typical examples of many modern chemicals (Figure 12). During a relatively short period (approximately two decades), a large amount of a specific material is consumed and accumulated in the anthropogenic stock. If, due to changes in technology or new information about environmental risks, the production of the chemical ceases, there is already a legacy of a large stock of the chemical to be managed in the future. For safe and efficient material management, it is important to assess the significance of a material before large amounts are accumulated in the anthroposphere. In any case, technology needs to be developed to treat and dispose of the large accumulation of stock of materials. For CFCs and plastics in construction materials, this could be energy recovery with state-of-the-art flue gas cleaning, producing mainly carbon dioxide, water, chlorides, fluorides, and concentrated metals, when properly incinerated in a modern municipal waste incinerator (Vehlow *et al.*, 1992, 1994; Rittmeyer *et al.*, 1993, 1994).

LEGACIES DERIVED FROM THE ANTHROPOGENIC METABOLISM

Modern economies depend on a high material turnover. The stocks they build up and maintain amount to several hundred tons of materials *per capita*. This is not only an economic fact, but also a cultural reality. Material growth is incorporated into Western culture; it defines progress like no other single criteria. Future generations will have to deal with this stock; they can use, renew, recycle or dispose of it. The materials contained in the stock can serve as future resources. They also imply future problems in so far as they contain hazardous substances. During and after the use of the stock, substances will be lost, and they will pollute the environment. The maintenance and disposal of the stock will bring about considerable costs for future generations. Will future generations value this stock as a precious asset or as a technology/economy brake?

It is undisputable that if the present metabolic rate is maintained, there will ultimately be constraints for development. These may occur as resource scarcities at the supply side, or as environmental degradation at the disposal side of the anthroposphere. Will these constraints become effective in decades, centuries or millennia? Probably the most important legacy from today's anthropogenic metabolism is the addiction to it. The high growth rates and large stocks became so attractive and convenient to consumers and producers that alternative economic and cultural models do not seem to be noteworthy, and other metabolic options are neither studied nor implemented to a significant degree. The metabolism of an affluent society seems to confirm the Latin saying *plenus venter non studet libenter* (a full stomach does not like to study)!

Cities as Hot Spots

The largest anthropogenic material stocks have been built up in cities. Soon, more than half of the world's population will be living there, thus the urban stock will continue to grow. From a materials management point of view, this is an advantage. Human needs can be fulfilled more efficiently and with less supply of materials and energy in a densely populated area. From an environmental point of view, the same applies. Environmental protection measures are more efficient if many people are connected to a compact urban system than if the same number of persons are joined through a wide and sparse rural system. On the other hand, the material flow density in cities, expressed, for example, in mass per time and area, or in mass per deposition rate, is orders of magnitudes higher than in most rural areas. Modern cities are material hot spots containing more hazardous materials than most hazardous landfills. The case studies of plastics and CFCs exemplify the large stocks of anthropogenic materials. This stock is not managed nor has it been noticed yet. It is built into the urban infrastructure in a way that does not allow one to economically recover the materials without losses. On the contrary, many materials are used so that re-use becomes impossible, leaving a large mass of hibernating materials in cities. In particular, underground networks for the transportation of water, sewage, energy (gas, electricity) and information are not yet recoverable when their lifetime is over. Other examples are materials used to prevent corrosion and weathering (e.g., surface coatings, pigments),

such as zinc and copper. The emissions from these sources surpass the flows from point sources such as production facilities.

Cities are also hot spots for flow-through materials. In particular, nitrogen is of long-term concern, since this is an essential element for human nutrition. Wastewater treatment technology will have to be improved, and costs will rise, if large river systems and estuaries are to be protected from nitrogen overload. Alternative wastewater management concepts may become competitive, if urbanization continues to increase the nitrogen flows to surface waters.

While the dietary nitrogen emissions cannot be tackled by a prevention strategy, carbon dioxide flows, which are mainly produced for transportation and room heating, can. From a technical point of view, these emissions can be avoided by switching from fossil to solar energy sources. Thus, to tackle the hot spot city, a multi-facet strategy is needed, including prevention, new technologies and state-of-the-art waste management.

Limits at the Back End and Not at the Front Side

For most of human history, the anthropogenic metabolism was limited at the supply side. The foremost challenge of prehistoric mankind was to find enough food and shelter to meet essential needs. The development of civilization was accompanied by increasing requirements for supplies beyond basic physiological needs. Since the beginning of history, the search for energy and raw materials has led to many innovations, conquests, and wars. Today, the need for resources is greater than ever, the rate of consumption is large and growing, and a fair distribution of goods seems a much bigger challenge than exploitation of resources. At the beginning of the third millennium, the supply problem has been solved by modern technology, and severe resource limits at the front end are not in sight in the next few decades.

Today, the new question arises at the output side of the metabolism: how can we safely dispose of the very large amounts of waste materials? The need for resources is paralleled by the need for final sinks for these resources. This challenge is new. Never before has mankind had to care about the dissipation of anthropogenic materials on a global level, such as carbon dioxide or CFCs, although industrial activities always relied on the dissipation of residues in air and water. In the 20th century, the anthropogenic energy metabolism depended on the seemingly unlimited possibility of dispersing CO_2, the main product of energy conversion, in the atmosphere. However, CO_2 dispersal is no longer acceptable because of the concern about global climate change. This will require fundamental changes in the future anthropogenic metabolism, since, for example, a solar energy supply will result in significantly different material needs than a fossil fuel supply.

The search for appropriate final sinks is not only important for linear flow-through materials such as carbon and nitrogen compounds. Ultimately, materials in the stock and materials recycled need to be disposed of in final sinks as well. Up to a certain level, materials can be diluted in the environment without negative effects. On a global level, the limits for dissipation are not yet known. The controversy about carbon dioxide emissions causing greenhouse effects and leading to climate change shows how difficult it is to define these limits. Considering the large exploitation of metals displayed in Figure 2, two questions arise: where are these minerals now (in use, hibernation, in landfills, or dissipated in water, air and soil?), and where should they finally be? Neither question has been adequately addressed so far. There are no global inventories of the most important resources yet. While information about mining and primary production is abundant, data about product use and consumption are much more limited. Besides a few exotic examples such as gold and plutonium, there is very little information about the stocks, and there is virtually no systematic information about the fractions of materials already dispersed in soils, sediments, water, air, or landfills.

The Soil as a Long-Term Sink and Source

Sinks for anthropogenic materials either transform organic substances into mineralized natural materials (e.g., organic compounds are transformed to carbon dioxide and water) or store immobile inorganic materials safely for long time periods. They include:

- the atmosphere, where organic emissions may be transformed by reactions such as photolysis;
- the soil, where materials are deposited by atmospheric deposition, by agricultural and industrial practice, and by waste management;
- the sediments, which trap the pollutants imported into lakes and oceans by rivers and atmosphere.

If a sink for metals and inorganic matter is defined as a sphere on the globe where materials have residence times longer than several centuries, the soil may be called the most important sink, either for dispersed materials, or for wastes in landfills.

Material balances such as the cadmium example in Figure 4 reveal for all scales (local, regional, global), that, in general, the anthropogenic input of metals into regions is larger than the output (the sole exceptions are mining areas). The difference between the input and the output is in part built into the anthropospheric stock, in part accumulated in the soil because of atmospheric deposition, direct agricultural input or land filling with wastes. Soil monitoring programs confirm the results of material balances. They show increasing concentrations of heavy metals, organic chemicals, and phosphorous in soils, with

doubling rates for concentrations from decades to centuries. These accumulations have long-term consequences. On the one hand, there is now a phosphorous reservoir in many agricultural soils, which can supply valuable phosphorous. On the other hand, in mountainous areas, this stock is subject to erosion and is gradually transported to surface waters, causing eutrophic lakes for long periods, even if the agricultural application of phosphorous is stopped. The soil is only an intermediate sink for phosphorous, and it is a long-term source as well.

The same legacy corresponds to several metals in soils. According to the soil properties and the metal inputs, cadmium, lead, zinc and other heavy metals accumulate in soils, and may pose a future threat to food production and quality. This is a long-term process. Soil conditions, which are determined by the underlying rock formations, the rate of soil creation, inputs from the atmosphere and farming, and agricultural practice, are in a state of constant change. It is not possible to predict atmospheric deposition, soil use, and agricultural practice for long periods such as centuries. Therefore, since chemical speciation, and thus the availability of metals, depends upon the changing soil characteristics, a truly long-term forecast of the availability of heavy metals is difficult if not impossible. Stigliani talks about chemical time bombs (Stigliani, 1991) (*see* Contaminated Lands and Sediments: Chemical Time Bombs?, Volume 3). This is the reason why some nations have chosen to apply the precautionary principle, and to limit total concentrations of heavy metals in soils. The question remains what should be done once these maximum values are reached, which in densely populated, affluent areas is likely to occur within the next few centuries. A safe strategy for long time periods would be to adjust all inputs into the soil to the outputs, trying to balance soil concentrations continuously. This would require a large effort in air pollution control, cautionary and balanced agricultural practice, and considerable improvements in waste management concepts and practice. Such a challenging strategy does not appear feasible at this time.

Waste Management as a Future Key Process

The goals of waste management are to protect humans and the environment, to conserve resources such as energy, materials and land, and to reduce long-term risks from the disposal of wastes to an acceptable level. Hence, waste management is the paramount means to control the flows from the anthroposphere to the environment in a systematic and efficient way. In particular, land filling has a very important function. It must ensure that the large quantities of materials obtained from the ground find a long-term safe final storage place. A final storage landfill is defined as a (mainly inorganic) landfill with low emissions that do not alter the material flows in the surrounding environment (ground and surface waters, atmosphere) for long time periods (>1000 years). For most wastes, this can be achieved only if the wastes are mineralized and then immobilized.

The amounts of materials under waste management will increase because of rising consumption, and the huge amounts of materials in the stock that has to be renewed. Waste management inherits most of the materials in the stock. The composition of the long-living stock is more hazardous than the short-lived consumer products, which are recycled today, such as packaging materials. Even if recycling is extended, there will be large and rising amounts of metals and organic substances to be treated and disposed of safely. Waste management systematically closes the anthropospheric cycles of materials, giving them back to the Earth s crust in a controlled and environmentally sound manner.

Recycling is only an intermediate and not a nal solution for materials management. It does prolong the residence time in the anthroposphere, but for thermodynamic reasons, recycling cannot prevent the need for an ultimate sink. Recycling can be an excellent means to reduce the overall environmental impact of those materials requiring much energy and producing vast amounts of wastes and emissions during primary production. It also reduces the need for nal storage land ll space by decreasing the amount of primary material needed. However, recycling will not decrease the materials already used, and thus cannot change the future need for the disposal of materials already in the anthroposphere. At present, recycling is looked at primarily from a process technology point of view. In future, recycling has to be integrated into the design of new systems, processes and goods. The stock of a modern urban system can be ef - ciently extracted only if there is information available about the density and location of individual materials. As for geological exploration of natural resources, speci c tools are needed to identify and locate the future urban ores.

FUTURE STRATEGIES

The present metabolism of the anthroposphere is not sustainable for long periods of times. Emissions at the back end, the lack of appropriate sinks, as well as the scarcity of resources at the supply side, set limitations. The majority of the global population does not enjoy an af uent metabolism yet, but it has the same objective, i.e., to reach a similar material turnover as that of wealthier parts of the world. There are no signs yet indicating that in the future the developed world will break its growth path and slow down material consumption. Therefore, it is highly probable that global material ows and stocks will considerably increase in years to come. The rst warning signs are there already, such as the steady growth of the ozone hole, increasing greenhouse gas concentrations, nutrient overloadings in surface and groundwaters and others indicating that it is time

now to take action to redesign the present anthropogenic metabolism.

Today s situation may be compared to other ruptures in the development of society and technology, such as the introduction of industrial fertilizer or the change from biomass to fossil fuels for energy. Both of these changes allowed mankind to overcome severe constraints in the advancement of civilization. In the coming decades, equivalent changes in technology, economy and culture may occur. The anthropogenic metabolism must be redesigned to satisfy the needs for a global population based mainly on renewable resources without impairing the environment.

As a consequence, a new material management strategy is needed. Environmental considerations must become an essential part of material science. Decisions about material alternatives can be taken only if the fate of a material from source to final sink is known. Analysis and modeling of total material flows and stocks over long periods are needed. The availability of a final sink for all materials used is an important design consideration. If no appropriate final sink can be assigned to a material, it should be phased out and replaced. The possibilities and limitations of waste management to recycle and dispose of materials safely should be considered at the design stage. The new goals are that only three kinds of residues should result from the use of goods:

- residues and emissions that can be either completely mineralized or that can be safely dispersed in appropriate final sinks;
- clean residues suitable for multiple recycling;
- residues with final storage quality for which an appropriate final sink is available.

For modern economies with advanced environmental standards, emissions during consumption are relatively more important than emissions during production. This requires a shift of priorities in environmental management. Future measures must concentrate more on non-point sources, on consumer-related sources, and on the design of environmentally acceptable products; they must take into account consumer behavior and lifestyle. Also, a new awareness for materials must be created. At present, questions like Where is the final sink for this material? or How can this complex mixture be dismantled? are rarely asked by consumers and often not answered by designers.

In order to make better use of the stock, MFA must be supplemented by material accounting, i.e., the continuous monitoring of flows and stocks at a few key points of the anthropogenic metabolism. This allows for early identification of the accumulation and depletion of valuable resources, and for assessment of the future burden on the environment. In a competitive material economy, material accounting can result in a comparative advantage, as was the case when financial accounting was introduced.

City mining may eventually replace traditional mining of ores. Since the urban stock of materials grows constantly, cities become attractive concentrations of many minerals. If properly designed and maintained, it will be more economical to exploit the anthropogenic material stock than natural resources. Future urban areas may redevelop into partially industrial cities, taking advantage of their own stocks and taking a large part of their supply from their own domestic sources. Material extraction and transformation results in considerable amounts of waste energy, which in contrast to remote mining areas can be used in cities for heating and industrial purposes. The residues, which have to be land filled are much smaller for urban mining than for traditional mining.

It is not known how much time is left to counteract the negative effects of today s anthropogenic metabolism. In any case, the longer it takes until measures are introduced for better management of material flows and stocks, the larger the metabolic crisis will be. It is time now to take a close look at the way we manage materials, to start crucial research and careful experiments, and to make a next quantum leap towards a new anthropogenic metabolism which fulfils the needs of both mankind and the environment in the third millennium.

In a companion article in this volume (*see* **Contaminated Lands and Sediments: Chemical Time Bombs?**, Volume 3), William Stigliani draws attention to the impacts that climate change (and other types of global change) might have on the mobilization, and sometimes the immobilization, of anthropogenically produced substances in the environment. Sometimes the changes will take place long after the material had stopped entering the biosphere, and seemed to be safely buried in the sediments of a harbor, or locked up in the urban fabric. This behavior presents a major challenge to simulation modelers to model the long-term behavior of urban metabolism.

Industrial and Anthroposystem Metabolism

THOMAS E GRAEDEL AND ROBERT J KLEE

Yale School of Forestry and Environmental Studies, New Haven, CT, USA

Metabolism has a central role in ecological research. The word has two quite distinct meanings. One, which is organism-centered, is "the chemical changes in organisms by which energy is provided for the vital processes and activities, and new material is assimilated for growth and repair or replacement." The second definition is substance-centered: "the sum of the processes by which a particular substance is handled in the organism." Studies of the ways in which organisms use energy and the ways in which substances flow through and are transformed in organisms provide substantial insights into the ways in which organisms receive and utilize the nutrients on which they depend.

If one thinks of an industrial factory or group of facilities as an organism, the biological analogy can be used to define an industrial metabolism in which the flows of nutrients, energy, and water can be analyzed. Alternatively, the flows and transformations of a particular technological substance can constitute a study in industrial metabolism. Similarly, if the organism in question is a human system and its technological components operating over a geographical region (such as a city), studies of the flows of nutrients and energy constitute research in anthroposystem metabolism. Both of these new technological metabolic subjects are areas of active and productive research.

In ecology, metabolic studies have as their goal the understanding of the way in which an organism works. That is also the goal in industrial and anthroposystem metabolic studies, but there is an additional goal as well, i.e., the anticipation that a detailed understanding of anthropogenically-created organisms will generate ideas for improved performance - financial, environmental, or otherwise. In industrial and anthroposystem metabolism, we seek not only to understand the organisms under study more completely, but also to change them.

INDUSTRIAL METABOLISM

Industrial metabolism is the integrated collection of physical processes that convert raw materials and energy into finished products and residues. The basic analytical tool of industrial metabolism study is *materials flow analysis*. This tool works by highlighting the primary drivers of the system the flows of materials and energy. A generic materials flows diagram for today s industry is shown in Figure 1, highlighting the linear nature of traditional industrial processes, where little material is recycled. In contrast, nature s cycles and those of the more advanced industrial analogues tend to create loops and niche organisms to handle wastes and re-route essential nutrients throughout the system. Aside from the simple quantification of stocks and flows of materials, the materials flow analysis can direct the scientist or policy maker towards addressing hazardous materials, reducing excessive raw material inputs, controlling dissipative waste streams, and discovering opportunities to reuse or recycle materials or energy. The proscriptive nature of industrial metabolism studies includes attempts to find ways to modify the current structure so that it closely mimics the biological/ecological ideal of total utility of materials and energy, where residues become feedstocks to other metabolic processes.

Metabolism Surrounding a Firm or Industry

The industrial firm is the smallest basic unit of industrial metabolic study that yields useful system-wide information. Today s total industrial ecosystem is largely a disordered agglomeration of independent firm-sized industrial organisms. (As will be discussed in the following sections, tomorrow s total industrial ecosystem has the potential to resemble instead a modestly organized conglomeration of cooperative industrial organisms.) The materials flows that sustain an individual industrial firm and its products, processes, and facilities can be analyzed with the goal of highlighting wasteful materials and energy practices. For example, Figure 2(a) shows the total metabolic process for the creation of a generic automobile in a generic automobile manufacturing industry or firm in the 1990s. If the material

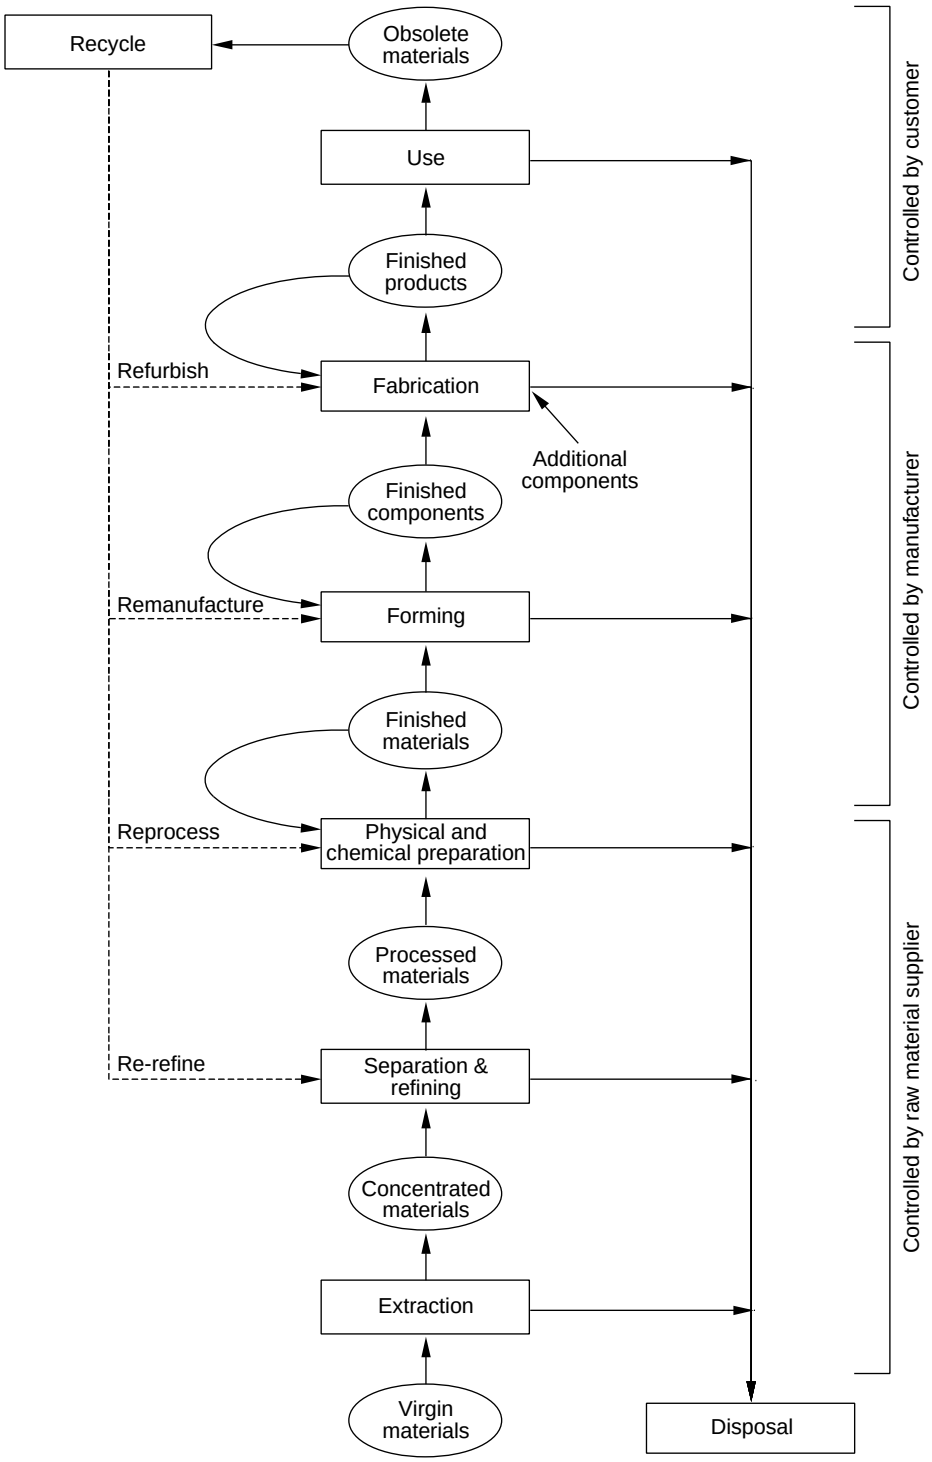

Figure 1 The total industrial metabolism cycle

ows and energy requirements are quanti ed, the rm can attempt to address inef cient system leaks and unrealized materials resources. Hence, Figure 2(b) shows an alternative look at the automobile ow diagram, focusing on the role that a single material in this case copper plays in the creation of a single generic 1990s automobile. An automobile manufacturing rm can use such a metabolic map of copper use per automobile to address points of material loss, as well as the environmental implications of materials choices through various life stages of a rm s product.

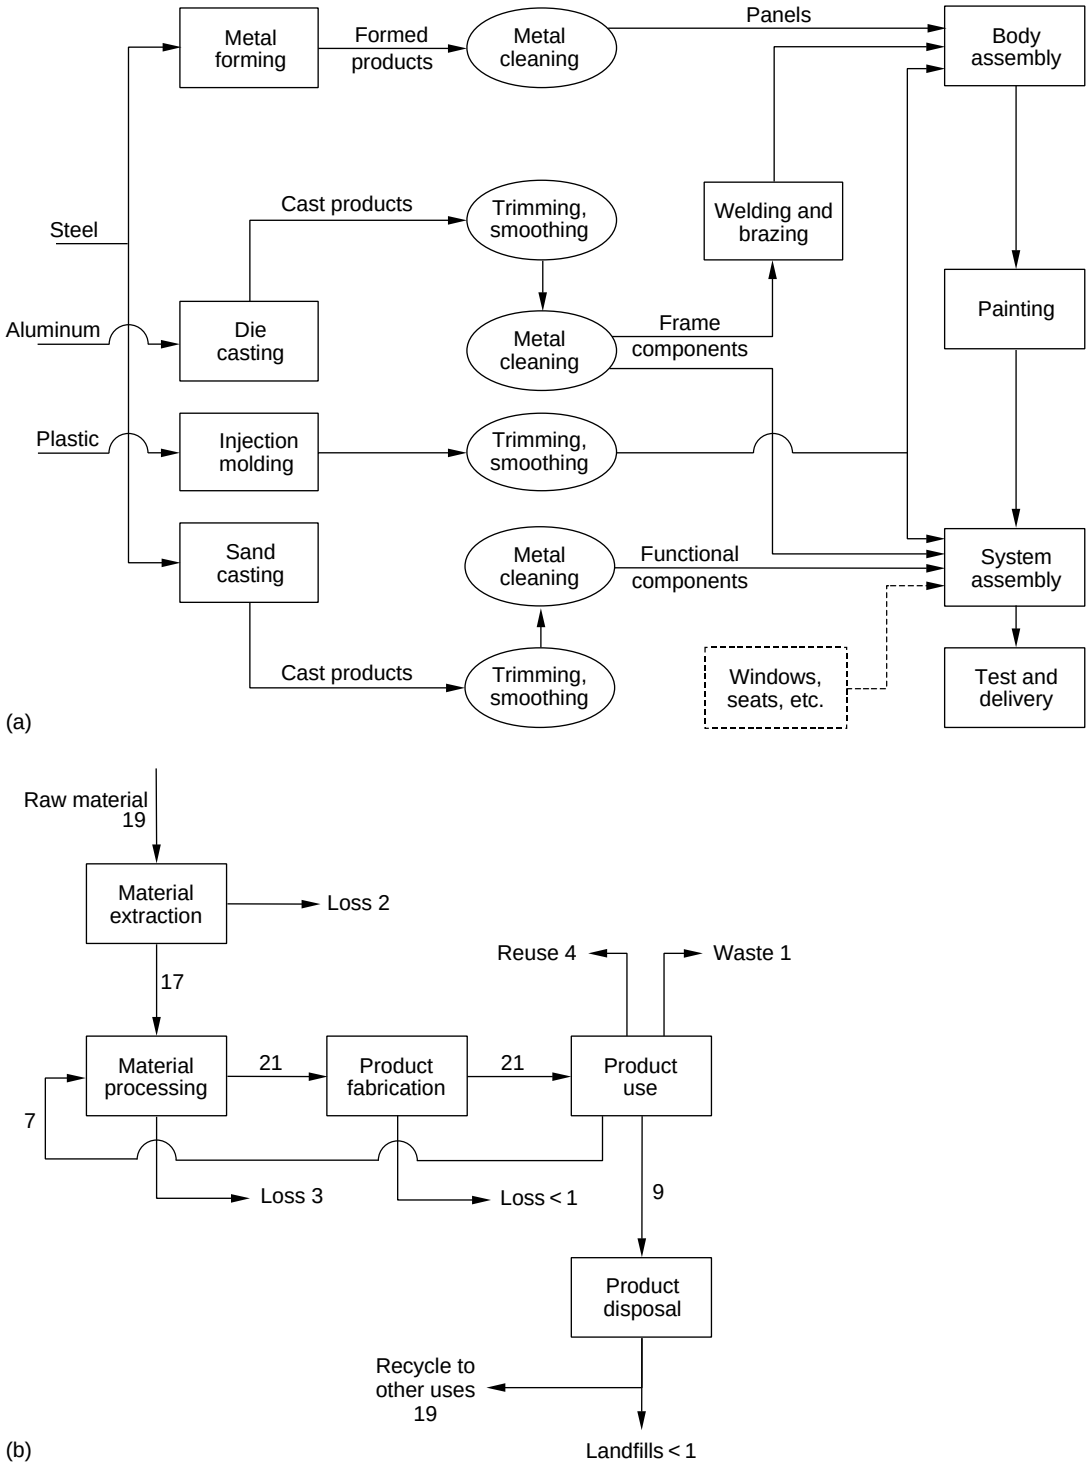

Figure 2 (a) Industrial metabolic processes for the manufacture of a generic automobile in the 1990s. Primary processes appear in rectangles, complementary processes in ovals. The boxes in dashed lines are included to indicate that only the principal metal structural components and their processes are treated, but that a more comprehensive analysis would indicate other components and their processes as well. (Reproduced by permission of Lucent Technologies from Graedel and Allenby, 1998). (b) The flow of copper (kg) in a typical 1990s automobile. (Reproduced by permission of Elsevier Science Limited from Ginley, 1994)

In either the industrial organism or industrial material case, metabolic studies tend to highlight inefficiencies in the industrial ecosystem at the firm or industry level. Firms can recognize under-utilized portions of raw material input that do not end up as part of the final product output, which is an economic and environmental inefficiency. The loss of raw material inputs is especially important when potentially harmful materials (such as lead-based solders, chromium-based plating compounds, and cadmium-based paints, among others) are part of the industrial system. Furthermore, a materials flow diagram can help a firm better understand its reliance on potentially hazardous intermediate process materials (such as aggressive acids or chlorinated solvents) that never end up in final products and almost always pose handling and disposal concerns. Environmental management initiatives can grow out of metabolic studies. For instance, firms might create an inviolate list of materials to assist product and process engineers in keeping hazardous and/or toxic materials out of the industrial metabolism, thereby reducing the potential social and environmental costs from manufacturing, use, and eventual disposal of the product.

Comprehensive metabolic studies would also include materials flows beyond the walls of an individual facility. Long before any processed material enters an individual firm, the extraction of raw materials has had a great potential for environmental harm, from energy use and subsequent air emissions, acid mine drainage, and aggressive chemical purification processes, for instance. Similarly, the use of a product once it is in the hands of a customer may have a great potential for environmental harm from energy use during operation of the product, dispersion of materials, and methods of disposal. Broadening the scope of a firm's vision to consider the upstream activity to support its operations and the downstream ramifications of its products is one of the first key steps in achieving a systems view of industrial activity. Through industrial metabolism analyses, firms can make educated choices that can have large positive influences both upstream and downstream.

In addition to addressing the potential hazards from industrial activity, a metabolic study may uncover a firm's reliance upon materials that in the long run will become increasingly scarce or will be fundamentally unavailable from natural sources. The adequacy of world mineral reserves can be determined by the depletion time of a resource. This measure is an approximation of the number of years before all known global reserves are gone, and is easily calculated by dividing the known reserves of a mineral resource by the rate of consumption of that mineral resource. Reliance on potentially scarce industrial materials is inherently unsustainable in the long term. A few potentially scarce yet commonly used industrial materials include: zinc (19 year depletion time), lead (20 year depletion time), cadmium (27 year depletion time), copper (35 year depletion time), and tin (40 year depletion time) (Kesler, 1994). A firm can address the scarcity issues raised in the metabolic analysis by finding ways to modify products and processes to use more abundant materials. In addition, the firm may uncover underutilized pathways to incorporate pre-consumer or post-consumer recyclable materials into products and processes, thereby addressing both potential scarcity issues and potential environmental hazard issues.

Metabolic results not only highlight potential hazards from a firm's industrial processes, products, and facilities or scarcity issues from materials choices, they may also direct fundamental conceptual shifts in the design process. Designing a product for the environment by excluding ecotoxic compounds or scarce raw materials, or designing a product for eventual recycling, should be considered concurrently with more traditional design considerations such as designing for durability, cost considerations, and ease of manufacture. Modifying the manufacturing process through educated decision making and environmental design has a much greater potential for environmental benefit than do the current end-of-pipe solutions for pollution emanating from industrial facilities.

Metabolism Between Firms

The next logical scale increment of industrial metabolism concerns the potential for creating a system of material and energy interchanges among individual firms. Interfirm industrial metabolic studies usually have a goal of identifying opportunities for reducing wastes and pollution by exploiting low value residues of certain processes (such as heat energy, water, or material) as raw materials for others. This is sometimes called *industrial symbiosis*, a term again borrowed from natural science, in which two or more industrial processes or firms are linked in a mutually beneficial exchange of resources or materials.

Eco–industrial parks (EIP) exemplify industrial symbiosis in action. An EIP may be best defined as a community of manufacturing and service businesses seeking enhanced environmental and economic performance through collaboration in managing environmental and resource issues. By working together, the community of businesses seeks collective environmental benefits greater than the sum of the individual benefits each company would realize if it optimized its individual performance only (such as reduced energy consumption and waste minimization). Economic benefits also flow from these environmental benefits, realized in costs avoided for waste disposal, reductions in raw material purchases, and from shared/centralized materials management services. Not to be overlooked are the social benefits that usually follow from EIP development,

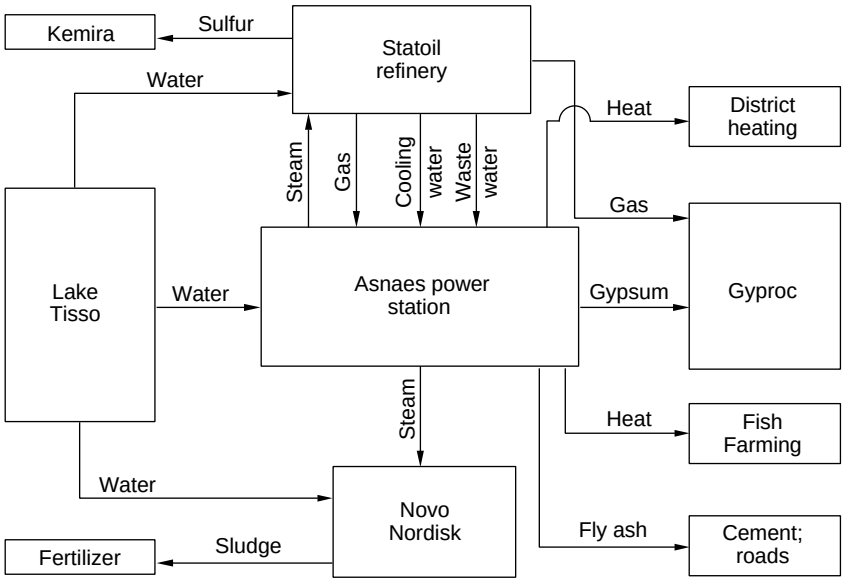

Figure 3 Industrial metabolism governing the town of Kalundborg, Denmark. Kalundborg's industrial network behaves very much like an ecological food web, where industrial organisms consume each other's waste materials and energy, forming bonds of interdependence. The Kalundborg eco–industrial system includes five core partners: the 1500 MW coal-fired Asnaes power station, the Statoil Refinery, the Gyproc plasterboard manufacturer, the Novo Nordisk pharmaceutical company, and the City of Kalundborg. The power station provides waste steam heat to the 20 000 residents of Kalundborg (for home heating) and to the Novo Nordisk pharmaceutical company and Statoil oil refinery for their industrial processes. The power plant uses fresh water for cooling and a small portion of the waste heated water is transferred to nearby aquaculture fish ponds, and uses a portion of surplus refinery gas from Statoil for power generation to supplement coal burning. A local cement company utilizes the de-sulfurized fly ash from the power plant. The power plant influences the sulfur dioxide (SO_2) in the stack gas with calcium carbonate to produce calcium sulfate (gypsum), which is in turn sold to Gyproc. The refinery provides excess gas (that otherwise would be flared off) to Gyproc as a low cost alternative fuel source. The refinery's de-sulfurization operation produces pure liquid sulfur that is sold to a nearby sulfuric acid producer, Kemira. Sludge from the fermenting and other biological processes at Novo Nordisk and from the fish farms are used as fertilizer in nearby farms. Local farmers use surplus yeast from the insulin production as pig food

including fostering a sense of community among businesses and surrounding neighborhoods.

The archetype for the EIP is found in the small town of Kalundborg, Denmark, where bilateral business agreements were developed over 25 years among large industrial firms in the business and social community of Kalundborg. Participants realized economic and environmental benefits through these agreements, and only towards the culmination of the 25 year development did they become cognizant of the industrial symbiosis network they had created. Figure 3 outlines the major flows of materials and energy that drive the system at Kalundborg. The Kalundborg model of industrial development, based on metabolic principles, can serve as a model system for a broad range of new and existing industrial systems to emulate.

The fundamental principle behind inter-firm industrial metabolism is that there is no such thing as waste, there are only under-utilized resources waiting to be exploited by an as yet unidentified industrial firm. For inter-firm industrial metabolism to work, residues must be in a usable form: at appropriate temperatures and pressures, in an economically viable quantity, in a reliable and steady supply, and free of hazardous contaminants. These are the engineering and technical challenges that face future creators of Kalundborg-like systems. Their achievement will require creative thinking and fundamental modifications of the individual firm s industrial metabolism in some of the ways outlined in the previous section.

ANTHROPOSYSTEM METABOLISM

The complexities at the scale of the rm and industrial park have historically obscured the vision of industrial processes and system interactions at regional, national, and global scales. At these scales, the complex interplay of individual rms and industrial systems with human and social constructions can create system problems not readily apparent nor explicitly felt by a single rm. Industrial metabolism, with its focus on products, processes, and facilities, is a term that appropriately addresses the metabolism surrounding individual rms and between rms. However, new thinking is required to directly incorporate human actions within a metabolic framework. The metabolism of a human system and its technological components includes

materials and energy flows, products, industrial processes, and facilities interacting over complex spatial and temporal scales. Although the more common term *urban metabolism* nearly covers all of these interactions, a broader term is more appropriate for the regional, national, and global metabolism, which are not wholly urban. We offer the term *anthroposystem metabolism* to represent the metabolic processes of human technological and human social systems at all spatial scales, broadening the basic principles of urban metabolism to include all of the technical and social constructs that support the modern technologically-related human.

Metabolism of a City or Urban Region

A city is a concentrator of resources and a generator of residues. A generic metabolic image of a city is shown in Figure 4. A typical modern city draws resources from the entire world, including energy, water, food, and a great variety of processed materials such as vehicles, structural steel, and furniture, among many others (*see* **Ecological Footprint**, Volume 3). Its transformation processes include the human food cycle, the combustion of fossil fuel, and the wearing out or gradual obsolescence of manufactured products. Leaving the city are a variety of residues of little perceived value: air pollutants, wastewater, and large, heterogeneous amounts of solid wastes. These various residues are dissipated in a number of ways and over various distance scales, but the dissipation lengths are much shorter than the original acquisition lengths.

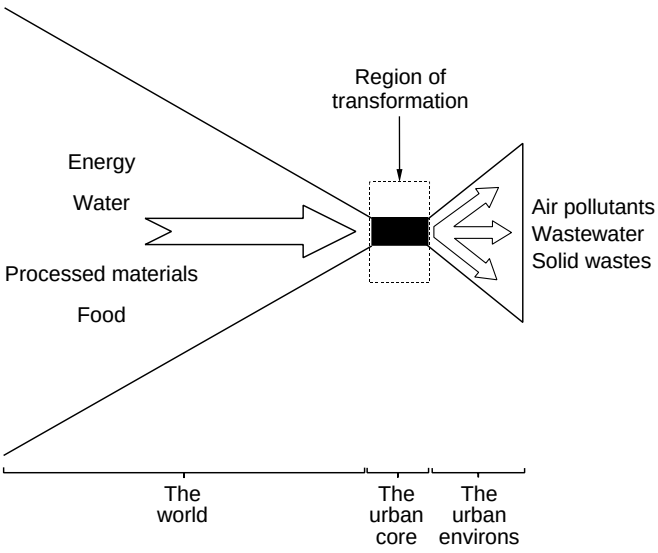

Figure 4 Generalized materials flows of urban metabolism. Materials are transported from throughout the world (a vast spatial scale) into the urban core, are transformed in order to sustain the human population, and are then released as wastes into the urban environs, a significantly smaller region adjacent to the urban core

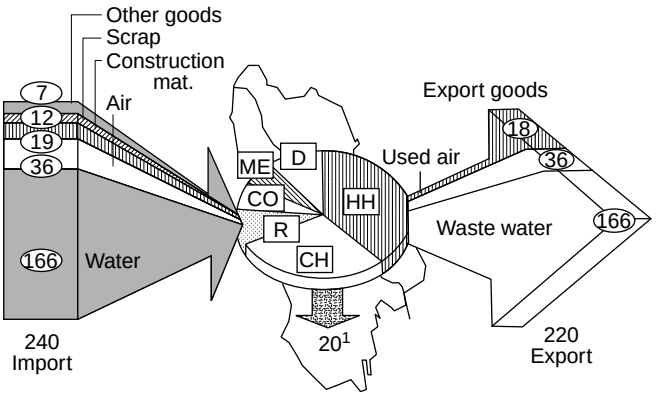

Figure 5 Flux of goods through the urban metabolism of the Bünz Valley, Switzerland, in metric tons capita-year^{-1}. HH, private households; CH, production of chemicals; CO, construction; ME, metal processing; FD, processing of food and drink; R, others. (Reproduced by permission of The United Nations University from Brunner *et al.*, 1994)

An example of an urban metabolic analysis is shown in Figure 5 for the Bunz Valley in Switzerland. Several facets of the analysis deserve comment. The first is the sheer magnitude of the flows: 220 metric tons person^{-1} year^{-1}, on average. Also of note is that the most abundant resource flow, by far, is that of water. The water is not retained; it passes through the system in various ways and leaves as part of the resource outflow. The same is true, though at substantially lower throughput, for air used in combustion processes. The resource flows with more complex fates are those of industrial chemicals and metals; of the 58 tons capita^{-1} year^{-1} that enter the region, 20 (more than a third) do not leave. Rather they are added to the built stock, namely roads, equipment, housing, and so forth (Brunner *et al.*, 1994).

Any environmental impacts attributable to the flows of resources in the urban metabolic system result from the residues. Interest in environmental impacts thus encompasses not only the magnitudes of the residue flows, but also their chemical form and the ecosystems into which they are dissipated. As with industrial metabolism, urban metabolism thus studies reservoirs of materials and the flows among the reservoirs. Unlike the more general industrial metabolism, however, that of urban areas refers to a specific location and thus to that location s logistical and environmental constraints. Where industrial metabolism implies an environmental relationship, urban metabolism explicitly addresses the environmental dimension in space and time.

Metabolic studies of the urban environment will be necessary to solve the frequently encountered problems of failed urban systems, in which the urban environs is under-provided with freshwater, energy, and raw materials, and is overwhelmed by sewage and industrial pollution. Many of the lessons and initiatives used in the industrial

metabolism example described above apply equally to urban metabolism. Most of today s cities were built at a time when resources seemed cheap, abundant, and infinitely available. Now we realize that financial and environmental costs are high, many resources are scarce, and none is infinitely available. Our modern urban areas currently require a high level of materials and energy use to sustain them. Urban metabolic health is largely determined, as with that of any organism, by the adequacy of the supply of sustaining technical nutrients and by the efficient removal of wastes. When the materials movement requirements of urban areas exceed the natural and/or technological capacity, the urban metabolism is inherently unsustainable. Thus, at some critical population density, materials movement systems may be unable to provide a sufficient quality and quantity of raw materials inputs and may be unable to remove the wastes that have the potential to poison the urban organism. Finding ways to turn wastes into useful materials is one notion that could greatly ameliorate this problem.

Land itself has become waste in many urban areas, as a repository for technological materials that leak out of the urban metabolic system. Inefficient metabolic activity (highlighted through materials flow analysis of urban areas) can poison the urban organism through heavy metal pollution, smog, and toxic waste, making these areas unfit for use without costly and time-consuming remediation. In the case of many older cities, established factories and waterfront areas have been abandoned for new industrial sites in the suburbs or in isolated industrial parks, leaving behind unsightly and unusable land. In response, new brownfield regulations allow reclamation and remediation of degraded urban industrial land to levels safe for future industrial activity, even if the soil is not quite fit for children to eat. This recycling of neglected urban sites generates environmental and economic benefits, while solving a problem of decay within the urban organism. As the brownfield story highlights, understanding and locating potential problems through materials flow analysis is the first step towards finding innovative solutions.

Data from a wide array of population studies, environmental science assessments, and human health statistics show that rapidly worsening urban environmental problems may dominate environmental discourse throughout the 21st century. Metabolic studies show the strengths and weaknesses of the structure of the typical urban organism, yet the more pressing question is whether or not the current urban metabolic system can accommodate the inevitable population growth. The data in this regard are truly staggering. In 1950, only 30% of the world s people lived in cities, a global total of 734 million urban inhabitants. By 1995, the world s urban population had more than tripled to 2.5 billion about 45% of the world s population (*see* Urban Population Change, Volume 3).

As is too often the case, the greatest potential for environmental degradation will occur in the poorest countries and in developing countries with the highest economic growth rates. This local environmental pressure will manifest itself in various failures of the metabolic systems that should move materials, energy, and wastes. The symptoms of this metabolic collapse will likely include increased pollution of urban water sources, diminishing supplies of fresh water, increases in numbers of cases of diarrheal diseases, heavy metal loading in urban soils, and general ecosystem damage, among others. Metabolic studies are important first-step tools to help guide urban development policy in answering the difficult questions of how to create a significant number of sustainable new cities, and how to design sustainability into expanding mega-cities. The mega-city, a phenomenon of the late 20th century, has materials and energy requirements at magnitudes well beyond our current rudimentary understanding of how to handle them appropriately. The mega-cities of today already suffer from inefficiencies in moving materials and wastes. The daunting number and complexities of energy and materials pathways in a mega-city have yet to be tackled in any rigorous manner, yet the mega-city is the most likely way in which burgeoning urban populations will be incorporated into the planet s urban fabric. This is the challenge for researchers of the urban metabolism how to sustainably accommodate urban growth in some of the most challenging social, political, and economic environments.

For a study of the metabolism of Vienna, *see* Anthropogenic Metabolism and Environmental Legacies, Volume 3.

Metabolism of a Nation or the Globe

On the national scale, metabolic studies have the potential to show a very broad picture of the materials requirements of the technological society, as well as the individual material responsibility of a person living in our material world. As shown in Figure 6, over 50 kg of material and energy inputs (not including water) are required to satisfy an average American s wants each and every day. At this rate, a person consumes 1600 metric tons over the course of an 80 year life, a mass that would occupy a cube almost 18 m on a side. The lesson from this metabolic analysis is that our current resource use and inevitable waste generation is inherently unsustainable. Furthermore, this analysis also gives a first-order approximation and valuable insights on the level of materials use and waste production to be expected when the entire world strives for a developed world standard of living. Quantification, even if only at order of magnitude accuracy, quickly shows the unsustainable nature of our current industrial metabolism when extrapolated into the future, assuming population

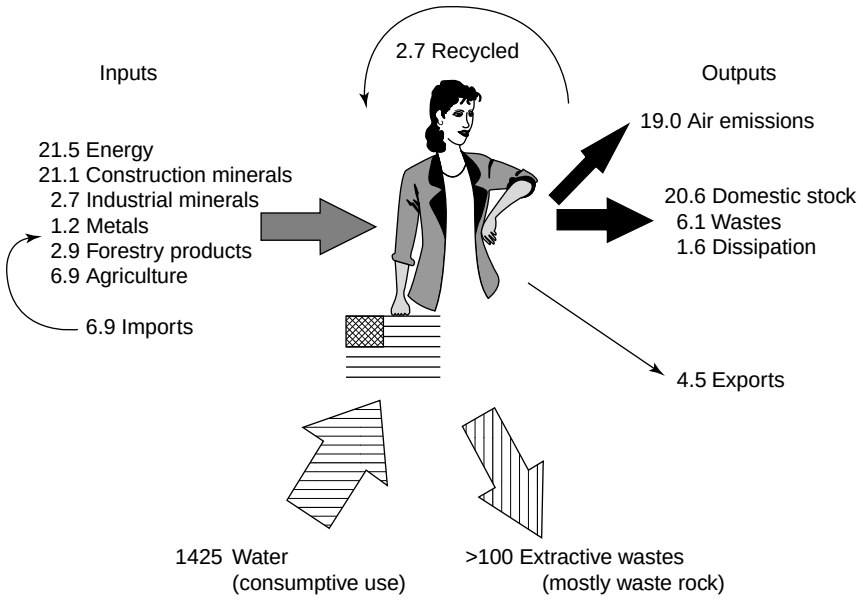

Figure 6 US Material flows, circa 1990, in kg capita-day^{-1}. (Reproduced by permission of Annual Reviews Inc. © 1995 from Wernick and Ausubel, 1995)

growth and greater *per capita* consumption of energy (*see* **Ecological Capacity**, Volume 3).

In addition to understanding the total material movements of a nation, the speci c fate and transport of potentially harmful materials require individual metabolic analyses. One of the most well documented heavy metals released to the environment by industrial processes and products is lead. The dangers of exposure to high levels of lead have been understood for centuries (in fact, acute lead poisoning has been documented for workers at ancient Roman lead smelters in Spain and England). Beginning in the 1970s, epidemiological studies reported adverse effects on child development at extremely low levels of lead exposure. Furthermore, the discovery of lead in ice cores from glaciers in Greenland showed that anthropogenic lead could travel great distances. This led to sweeping reform in industrial use in lead and the eventual removal of lead from gasoline in many countries. Metabolic analyses like that in Figure 7, which pictures the US ows of lead, can help direct researchers and policy makers in controlling releases of potentially harmful substances from a nation s industrial activity. Metabolic study helps differentiate between uses of a substance that are inherently dissipative (such as lead additives in gasoline) and therefore unrecoverable, readily bio-available, and potentially harmful to humans and ecosystems, from those uses of a substance that are inherently concentrated (such as lead in batteries) and therefore nearly in nitely recyclable, not bio-available, and sustainable over the long run with effective control systems.

The sum total of the industrial metabolic activity of all nations comprises the ows that determine the degree to which human activity disrupts global biogeochemical cycles. Just as considerable enlightenment is provided by materials ow analysis at local, regional, and national scales, global budgets and cycles of common industrial materials will yield insights on the sustainability of resource consumption and the dispersion of potential hazards through the world environment at concentrations greater than the natural ows. These materials ow analyses can direct policy and action towards the potential untapped reservoirs of previously exhumed and processed raw materials, e.g., materials in semi-permanent structures (buildings, roads, bridges, and the like), or in industrial and municipal land- lls. Detailed materials ow analyses have the potential to uncover untapped resources that could be recycled back into productive uses, commonly referred to as *mining the landfill*, even though these potential resource stocks are not limited to land lls. Tracking the global stocks and ows of common industrial materials is an area of active and growing research that will be of increased importance as global resources dwindle and the rami cations of systemic disruption of global biogeochemical cycles are better understood.

THE UTILITY OF METABOLIC STUDIES

While it is interesting to think of industrial systems and anthroposystems as organisms and ecosystems, such an activity is more than merely an intellectual exercise. It is rather a framework that permits us to examine the bene ts to be derived from studies of industrial or anthroposystem metabolism. These bene ts may be grouped into three categories, as indicated below.

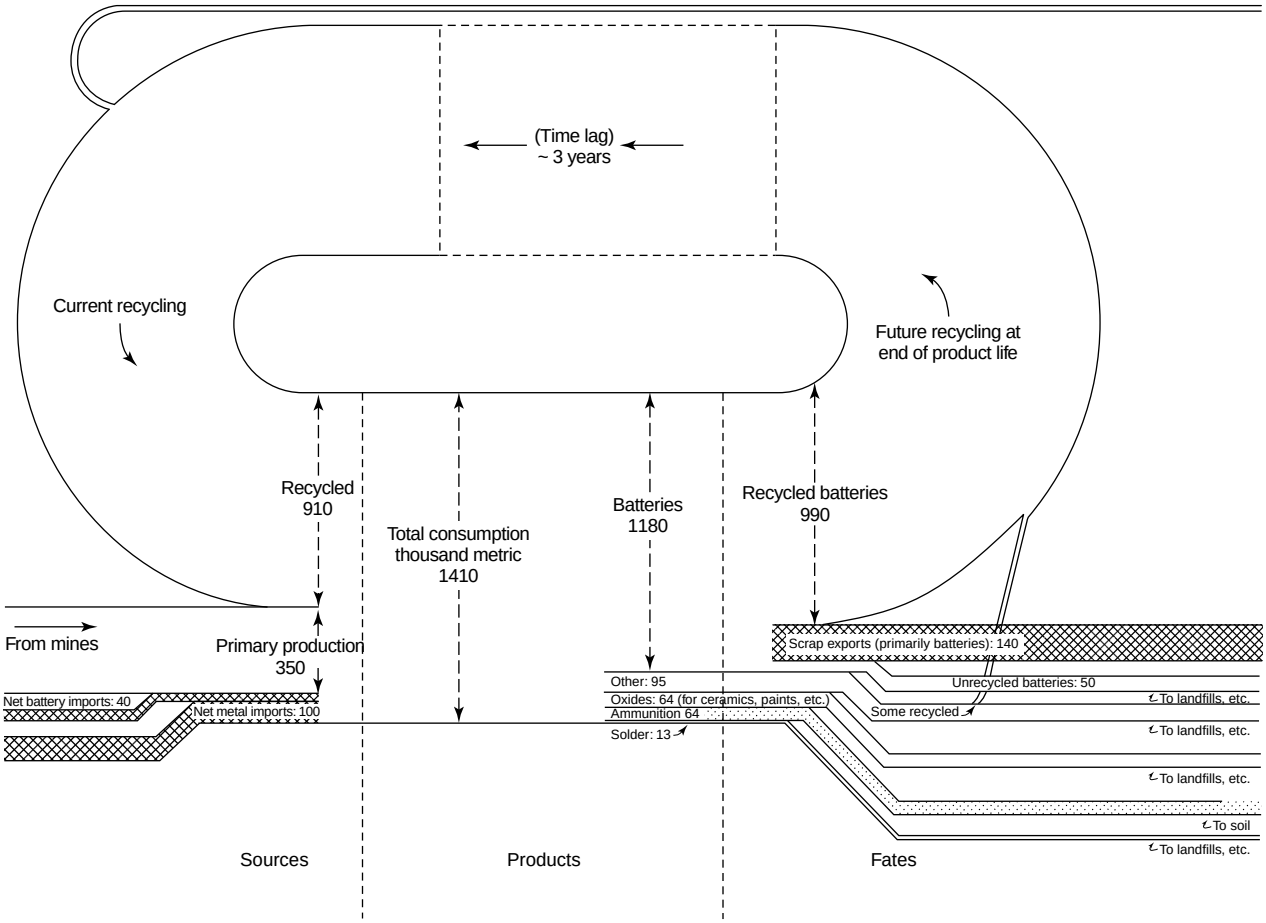

Figure 7 Flows of lead through the US economy in 1993–1994. Data displayed are averages of data for 1993 and 1994, in thousands of metric tons of lead year^{-1}. Other products are bearings, brass, bronze, cable covering, caulking, lead, casting materials, pipes, and sheet lead. Emissions to water or air – the primary health concerns – are not shown because they are too small to be visible at this scale. Also not shown is the roughly 0.6 thousand metric tons of lead used in aviation gasoline (about a billion liters with a lead concentration of 0.4–0.8 g l^{-1}). (Reproduced by permission of Cambridge University Press from Thomas and Spiro, 1994)

Maintaining Human Systems

Industrial and urban complexes require that resources to support them be provided in sufficient magnitude and on a satisfactory time schedule. In the case of small industrial organisms and small urban areas, materials flows are seldom compromised by input or output capacity. As these organisms and ecosystems grow and evolve, limits to efficient connectivity often begin to emerge. In industrial systems, especially those in densely populated urban areas, these limits are often related to infrastructure.

Urban infrastructure roads, power lines, natural gas distribution systems, water supply systems, sewerage, etc. have not traditionally been designed with flexibility and expansion in mind. Furthermore, they are customarily placed out of sight (and out of mind) under streets, along railroad right-of-ways, within building walls so that they are difficult to study and difficult to modernize. A recurring problem in growing cities is that infrastructure is unable to keep pace with growth in population and in industrial and commercial activity. By studying and predicting requirements for material flows, industrial and urban ecologists can aid in new design approaches that have the potential to accommodate evolving needs or desires involving flows of resources of all types.

In a similar vein, industrial and anthroposystem ecologists can evaluate and anticipate limits involving the management of residues. Infrastructure is an issue here as well, but the assimilative capacity of the environments receiving the residues is crucial. Topics for study include the amount and characteristics of wastewater flows, the rate of generation of solid wastes, the disposal of toxic residues, and the like.

It is interesting and unfortunate that we have little in the way of a clear understanding of what the limits might be to resource supply and removal within densely

populated areas. Might we be better able to reuse materials if population density is high? Will high population density be acceptable from a social point of view? From an infrastructure point of view? Can we reasonably hope to make cities more densely populated than Hong Kong (• 2000 people ha• ^{1}), and would we want to?

Industrial and anthroposystem ecologists can respond to these issues not only by suggesting limits to supply and assimilative capacity, but also by working to develop alternative systems for delivering resources, for recycling materials within local metabolic systems rather than exporting them, and by finding ways to reduce flows while maintaining the services those flows now provide. These efforts may immediately determine the feasibility from a materials standpoint of reordering society with the goal of improving long-term sustainability.

Maintaining Environmental Systems

The continued existence of a planet suitable for supporting life is clearly an important thing to think about. It is also clearly a function of the environmental stresses placed upon the planet by human activities. The levels of these stresses now and in the future can be determined by studies of industrial and anthroposystem metabolism, as the following examples show.

The air in the Los Angeles Basin of California was clear and healthy until the middle of the 20th century. In the 1950s, however, a new phenomenon, photochemical smog, began to make the quality of the air progressively worse. Although motor vehicles had been driven around Los Angeles for many years, there were finally enough of them and the tailpipe emissions were voluminous enough that an environmental threshold had been exceeded. Future exceedences of this type may be predictable, and prediction will surely be possible only if the relevant environmental science is understood, the current residue flows have been determined, and future residue flows can be estimated.

A second type of environmental systems benefit from anthroposystem metabolism studies is the potential for determining the relative intensity of sources of residues. In a study of emissions of copper to the Swedish environment (Landner and Lindestrom, 1999), neither industrial activity, nor mining, nor roof runoff proved to be the dominant source of copper, as was anticipated. Surprisingly, residues from automotive brake linings were the source of copper with the highest flow rate to the environment. With this information in hand, Sweden was able to place less emphasis on dealing with unimportant flows of copper to the environment, and more on the crucial ones.

Redesigning Human Systems

Industrial ecology operates from the perspective that an ideal technological society is one in which materials, once extracted from their natural reservoirs, are retained in useful forms as long as possible through reuse and recycling. That is, technological resources should cycle just as do nature s resources. Such an achievement is only possible with considerable effort, i.e., if products are designed to use recycled materials, materials are used in ways easy to recover, and so on.

Industrial ecology further contributes to resource cycling by identifying previously unappreciated or unmeasured reservoirs that may contain reusable material. In a classic study of this type (Kimbrough *et al.*, 1996), David Allen and co-workers, then of the University of California at Los Angeles, studied silver loss to the San Francisco Bay as well as the industrial and societal use of silver in the same area. Two important facts emerged:

- Most of the loss of silver to the Bay occurred during X-ray film developing by small medical and dental offices. Once this silver source was identified, arrangements were made for regular pickup of discarded film developing baths. The result was an improved Bay environment and the recovery of silver for future reuse.
- Approximately 10% of all silver used was retained on developed X-ray film in medical and dental offices. Since the information on those films can now be scanned into digital form and stored electronically, the X-ray film represents a significant stock of silver that can be mined in the future as needed.

Although research such as this has thus far been rare, we can readily imagine that similar work will lead to information on other important but unappreciated reservoirs and on losses important to avoid in order to provide healthy environments.

CONCLUSION

One of the most crucial foundations for understanding the causes and consequences of global environmental change is the ability to anticipate and monitor the path of change. Studies of anthroposystem and industrial metabolism are analytical approaches that fundamentally measure human, industrial, and natural system interactions. Once we know as accurately as possible where we were, where we are, and where we are going, we can begin to make educated and informed decisions concerning how to modify the trajectory of global environmental change. Many of the examples highlighted above show the potential for metabolic analysis when coupled with the concepts of industrial ecology. Industrial ecology requires that industrial and human systems be viewed not in isolation from surrounding systems, but in concert with them, and that industrial and human systems try to emulate the natural ideal of optimized resource cycling. The overriding goal of current and future industrial and anthroposystem metabolism studies

is to ensure our long term survival and prosperity by providing the information we need to make informed decisions.

Water Use: Future Trends, and Environmental and Social Impacts

BRUCE MITCHELL

University of Waterloo, Waterloo, Canada

By the early 1990s, it was estimated that 22 countries had serious shortages of freshwater, and by the year 2025 it has been calculated that there could be 52 countries with a total population of three billion people facing serious water shortages. The regions most vulnerable to water shortages are South Asia, Africa and the Middle East. In contrast, most areas in North America, Europe and Latin America will be able to meet water needs.

Various factors contribute to growing water demand, with the most important being population growth, increasing urbanization, growing economies which are becoming more industrialized, technological change, climate warming, evolving social tastes and values, and government policies. Furthermore, as initiatives are taken to develop new water supply sources, there can be negative environmental and social impacts. For example, major new dams and reservoirs ood land, which may result in loss of agricultural production or the need to resettle people in urban areas, create habitats which support parasitic and waterborne diseases, and reduce or eliminate indigenous ora and fauna. Social impacts occur due to negative consequences for health, and the potential regional instability and even war that can emerge due to competition for scarce water resources.

In planning to meet future water needs, it is important to consider three types of future - probable, desirable and feasible. Too often, overemphasis is placed on trying to identify the most probable or likely future, and not enough attention is given to considering what might be the most desirable future. Sustainable development is one choice for a desirable future, and its achievement will require a strategy, which includes both provision of new water supply sources and changes in human patterns of water use.

DEFINITION OF WATER USE

Before being able to consider temporal and regional patterns, and future trends, of water use, it is necessary to be clear about the nature of water use. As Gleick (1996) has commented that water use can include many different ideas and it is often misleading and confusing . In his view, water use can be either withdrawal (intake) of water, gross water use (intake plus recirculation plus reuse), or the consumptive use of water. Other distinctions have been made. Kindler (1992) identified three different types of water use: (1) on-site; (2) intake; and (3) instream or flow. On-site use includes activities which deplete water supplies before they reach surface or groundwater systems. This category includes water taken by wetlands, natural vegetation, rain-fed crops, wildlife and evaporation. Intake uses involve situations in which water is physically removed from a supply source for domestic, municipal, industrial or agricultural purposes. Some of the water is returned to the natural system after use, but usually in a modified state. Instream or flow use is represented by water used for generation of hydroelectricity, navigation, fish and other aquatic life, and recreational activity by humans. This category of use usually is not consumptive and the water is subsequently available for other uses.

Kindler (1992) also distinguished between amounts of water withdrawn and consumed. Water becomes consumed when it is incorporated into a product, such as a beverage, or when it is lost to the atmosphere through evapotranspiration. Consumptive uses can sometimes result in the water becoming available for subsequent use, but not always at or near the place from which it was originally taken. Another distinction is made by Ayibotele (1992) when he refers to consumptive and non-consumptive uses (hydro power, navigation, fisheries, recreation).

NEED FOR WATER

It has been suggested that a country or region experiences water stress when supplies are less than

17 000 m^3 person^{-1} year^{-1}. To place this latter figure in perspective, Serageldin (1995) reported that the global average annual supply of renewable freshwater in the early 1990s was approximately 7400 m^3 person^{-1} year^{-1}. This average figure, however, masks the reality that in the early 1990s some 22 countries had renewable water resources of less than 1000 m^3 person^{-1} year^{-1}. The greatest shortages occurred in the Middle East and North Africa, while Latin America was the region with the greatest *per capita* abundance of water. Looking to the future, Serageldin (1995) stated that by 2025 up to 52 countries with a total population of 3 billion people could experience water stress or chronic water scarcity, relative to the threshold noted above.

Another study of 118 countries, completed by the International Water Management Institute, concluded that 1 billion people in northern China, western and southern India, Libya, Saudi Arabia, United Arabic Emirates, Kuwait, Oman, Jordan, Yemen, Israel, Egypt, Tunisia, Iraq, Iran, Syria, Afghanistan, Pakistan, South Africa and Singapore could be expected to face absolute water scarcity by the year 2025 (Seckler *et al.*, 1999). When those countries were combined with other nations expected to experience economic water scarcity , Seckler and his colleagues concluded that some 26% of the 1990 world population would experience severe water shortages. In contrast, countries in North America and Europe were estimated to be in the best position to meet their water needs by 2025.

Gleick (1996) has suggested that attention must be given both to the quantity and quality of water relative to four basic needs: (1) drinking water; (2) sanitation; (3) human hygiene; and (4) preparing food. Further details about these different basic water use needs are presented below.

Drinking Water

Notwithstanding that water needs for survival by humans are influenced by physical conditions and physiological characteristics, the variation in need is not large. Most humans begin to experience thirst after losing only 1% of bodily fluid, and are in danger of death when fluid loss approaches 10%. The minimum water requirements to replace lost fluid for a person in average temperate climate conditions have been calculated to be about 3 liters day^{-1}. If climate and activity levels are different, the daily water requirements change. For example, in a hot climate, it has been calculated that a 70 kg human will perspire between 4 and 6 liters day^{-1} without any significant change in food intake or activity.

Based on a review of estimates by a variety of research organizations, Gleick (1996) concluded that minimum water requirements for a human to survive in a typical temperate climate and involved in normal activities is 3 liters day^{-1}. In tropical or subtropical conditions, this minimum value is increased to about 5 liters person^{-1} day^{-1}, which also can be expressed as just under 2 m^3 person^{-1} year^{-1}.

Sanitation

Humans health usually requires access to safe potable water for consumption, as well as a sanitary way to dispose of human wastes. As discussed in the article in Volume 4 focused on the International Drinking Water Supply and Sanitation Decade (IDWSSD) (*see* IDWSSD (International Drinking Water Supply and Sanitation Decade), Volume 4), many people in the world, especially in developing countries, do not have access to either safe water supply or sanitation systems.

Technologies do exist which allow disposal of waste without use of any water, as shown in Table 1. On the other extreme, the most inefficient toilets may use more than 75 liters person^{-1} day^{-1}. The sanitation technology selected is a function of the development goals and capacity of a country or region, available water, and key cultural and social values. Given that sanitation technology does exist which uses no water at all, and the context-specific nature of water requirements for sanitation, it is difficult to establish one number regarding a minimum amount to meet basic sanitation needs. Technically, it is feasible to set the minimum amount at 0. However, as Gleick (1996) noted, several aspects suggest a number of 0 is not appropriate. First, additional benefits to health can be documented when up to 20 liters person^{-1} day^{-1} of clean water are available. Second, if economic factors are not prohibitive, cultural and social preferences favor water-based sanitation systems. Accessibility to some water for sanitation, along with accompanying education related to water use, can significantly reduce the incidence of diseases. As a result of these considerations, Gleick (1996) recommended that a minimum of 20 liters person^{-1} day^{-1} be used to reflect the benefits of combining waste disposal and associated hygiene, and to accommodate dominant cultural and societal preferences.

Source: Gleick (1996).

Water for Bathing

Beyond direct sanitation requirements related to disposal of human wastes, additional water is used for bathing (showers, baths). Research in North America and Europe indicates that average water use for bathing is approximately 70 liters person^{-1} day^{-1}, with the range extending from 40 100 liters person^{-1} day^{-1}. Comparable data from developing countries are not generally available or are not reliable. From a review of various studies, Gleick (1996) suggested that the minimum water needed for bathing is in the range of 5 15 liters person^{-1} day^{-1}, while that needed for showering is 15 to 25 liters person^{-1} day^{-1}. He has recommended that 15 liters person^{-1} day^{-1} be used as a basic level of service for bathing.

Water for Food Preparation

Studies of residential water use usually have not separated the water needed for cooking or food preparation. However, a review of work in developed countries has suggested that 10 50 liters of water are used for each person per day for food preparation, and that the average use is about 30 liters person^{-1} day^{-1}. Studies that have considered food preparation needs in both developed and developing countries have concluded that an average of 10 20 liters person^{-1} day^{-1} satisfies most regional needs. On that basis, Gleick (1996) concluded that 10 liters person^{-1} day^{-1} would meet most basic needs.

Water for Biophysical Ecosystems

The above discussion of basic needs is anthropocentric in that it focuses only on human requirements. However, other living species, which share the Earth with humans have basic water needs, especially fauna and flora associated with aquatic systems. Minimum flow requirements to meet the needs of natural ecosystem functions and processes are difficult to estimate, although attempts are being made, particularly in North America, Europe and Australia (Born *et al.*, 1998). For example, in 1999, a dam was removed from a New England river in order to allow the flow regime in a river system to function to meet the needs of fish in that aquatic system. In California, under various federal and state statutes, almost 30 000 million m^3 of annual runoff in river systems, or 28% of the total annual average runoff in the state, have been designated for environmental purposes, including fish, waterfowl, and wetland systems. While no specific number can be identified for all situations, it is important that those responsible for making decisions about water use needs consider the requirements of non-human users of ecosystems.

Table 2 Recommended basic water requirements for human needs[a]

Purpose (liters per person per day)	Recommended minimum (liters per person per day)	Range
Drinking water[b]	5	2 to 5
Sanitation services[c]	20 to over 75	
Bathing	15	5 to 70[d]
Cooking and kitchen	10	10 to 50[d]
Total recommended basic		
Water requirement	50	

[a] Excludes water required to grow food.
[b] This number is a true minimum required to sustain human life in moderate climate conditions and with average activity.
[c] An average (not minimum) of 40 liters person^{-1} day^{-1} is estimated to be adequate for direct sanitation hookups in industrialized countries. The upper end reflects very inefficient toilets. In regions in which water is extremely scarce, technology is available for sanitation systems, which use no water, but these are not usually socially accepted.
[d] The higher numbers in the range represent social preferences for moderately industrialized countries. Use in some water-abundant regions may exceed these amounts. The lowest values represent minimum uses in developing countries.
Source: Gleick (1996).

Summary Regarding Basic Water Needs

Following his analysis of basic water needs, Gleick (1996) concluded that international organizations, as well as national and local governments and water suppliers, should adopt a basic water requirement standard for human needs of 50 liters^{-1} person day^{-1}, as shown in Table 2. In his view, unless this basic need is met, large-scale human misery and suffering will continue and grow in the future, contributing to the risk of social and military conflict (Gleick, 1996). The information about minimum water requirements provides the context for the information and narrative provided in this article.

PATTERNS AND TRENDS OF WATER USE

Drivers of Use

Various factors drive water use. Key drivers are population, urbanization, nature of the economy, technology, climate, social values and tastes, and policy decisions, especially pricing. Estimates have to be made regarding each of these, before being able to make estimates about future water use patterns and trends. The uncertainty associated with the calculations for each of these drivers becomes compounded when such estimates become the inputs for calculations of future water use, emphasizing how easy it is for forecasts of water use patterns to be inaccurate.

Population

One of the most important drivers regarding future water use patterns is population growth. Ideally, to identify future trends of water use, information is required regarding the size and composition of the population, including data about size as well as age, sex, fertility rates, migration and death rates. Given the difficulty in assembling such data, attention often focuses only on the size of future populations.

The United Nations (UN) (1991) projected that the growth rates in percent per year between the years 2000 and 2025 could be expected to be 1.54% at a global scale, resulting in an overall population of 8.5 billion, compared to the anticipated 6.3 billion by 2000. In 1990, the developed countries had just under 23% of the global population, with slightly more than 77% in the developing countries. By 2025, if the population forecasts are correct, those percentages will be 16 and 84%, respectively (*see* Global Population Trends, Volume 3).

The implications for water use patterns are significant. As standards of living rise in the developing countries, *per capita* water use will steadily climb upwards. Furthermore, as the economies in developing countries become more industrialized, higher rates of water use can be anticipated. And, finally, with more people, there will be increased pressure to increase food production, which will lead to more initiatives to develop irrigation agriculture, even if that occurs on land not ideally suited to irrigation.

Urbanization

Not only will there be a steady overall population increase continuing into the 21st century, there also will be an increasing proportion of people living in cities (Stren *et al.*, 1992). Niemczynowicz (1996) stated that the world s urban population increased 2.5 times between 1960 and the early 1990s. By the mid 1990s, about half of the world s people lived in cities; by the year 2000, twice as many people were expected to be living in cities compared to rural areas. Furthermore, the number of megacities (cities with more than 10 million people) were expected to increase to 23 by the year 2000, 80% of which would be in developing countries. By the year 2000, Tokyo was expected to have about 30 million people, followed by Mexico City with just under 26 million, Sao Paulo with 24 million and New York City with 18.5 million. In terms of cities with more than 5 million inhabitants, it was expected that by 2000 there would be 60 (*see* Urban Population Change, Volume 3).

Niemczynowicz (1996) noted that the drinking water demand in megacities was growing rapidly, even though at a global scale, urban populations accounted for only about 15% of total water consumption. Much of the most rapid urbanization in developing countries has occurred in squatter areas, without any control or investment in supporting urban infrastructure. To illustrate, he indicated that 80% of the residents of Addis Ababa and 70% of the inhabitants of Calcutta lived in squatter areas and were not provided with access to safe potable water or sanitation facilities. When water supply systems were in place, they often were inefficient, with significant amounts of water lost to leakage. According to Niemczynowicz (1996), water leakage accounted for losses of 33% in Mumbai (Bombay), 36% in Chennai (Madras), 37% in Seoul, 49% in Bangkok, 50% in Cairo and 51% in Manila. Corresponding numbers for cities in developed countries were 12% in Munich, an average of 18% in Canadian cities, and 19% in Stockholm. Thus, increasing urbanization can be expected to contribute to greater pressure on water supply systems to meet basic needs for water use.

Nature of Economy

The evolution of an economy in a country or a region is significant for future patterns of water use. Two major implications arise. First, direct impacts occur as a result of water demands from different uses. Second, indirect impacts occur as a result of growing regional income and higher standards of living, which usually result in higher levels of water use. Thus, it is important to be able to estimate both the size and shape of future regional economies (Landsberg, 1964). Indicators or measures often used are gross national product, individual spending, government investment, and private sector investment.

Estimating the nature of a future economy is fraught with difficulties. Calculations are required regarding the number and mix of industries (manufacturing, service, etc.), the future demand for goods and services, the comparative advantage of a region relative to competing regions, and effects of changes in public policies on the economy. Water is usually a minor cost relative to total production costs, but when real water scarcity occurs, it can be a significant constraint on economic development.

Technology

The role of technology is always difficult to factor in, since it may increase or decrease water use. For example, Sewell and Bower (1968) suggested that technological change can affect products as well as processes used, raw materials involved as inputs, and methods for handling water. Landsberg (1964) highlighted these considerations when noting that industry uses water in many ways. Water may be an ingredient in some products, be used to cleanse materials during production, be a medium for transporting material within a plant and be an agent for many chemical processes. However, by far the greatest proportion of water withdrawn for industrial use is for cooling, accounting for more than 80% of all water consumed in petroleum refining, chemicals and non-ferrous metals, about 70% in the iron

Box 1 Uncertainty created by technology

The large amounts of water used by industry for heating and cooling are at the heart of the problem of estimating industrial demand. The many technical substitution processes available for water conservation in industry all have different costs and performance characteristics (Gupta, 1992).

and steel industry, and 50% in the food products industry (see Box 1).

To reduce water use, industry has adopted many approaches to handle cooling processes. In some instances, air cooling and/or brackish or seawater has been substituted for fresh water. As Landsberg (1964) remarked, Revolutionary technological and scienti c advances could drastically affect the future demand outlook. Conceivably, a type of air cooling that uses no water whatsoever might be substituted for conventional cooling processes . Changing technology relative to irrigation practices also could signi cantly reduce the amount of water required to support agricultural production in many parts of the world. In a similar way, a major innovation in design of toilets could signi cantly reduce domestic water use.

Thus, to estimate future patterns of water use, it is desirable to be able to incorporate the likely effects of technological change on water use. Needless to say, this is not an easy task, since it is not always possible to know which technological innovations will occur, nor which ones will lead to either reductions or increases in water use.

Climate Warming

Scienti c agreement is growing that climate warming is occurring and that it is likely to continue well into the next century. High-latitude countries will experience more warming compared to low-latitude countries. However, even within regions or countries with a large spatial extent, there can be signi cant variations in the implications for hydrological systems. For example, Arnell (1999) prepared four scenarios to the 2050s related to the effect of climate change for hydrological conditions in Europe. He concluded that there would be general reduction in runoff in southern Europe (south of latitude 50°) but increased runoff in northern Europe. Overall, lower summer ows could be expected along with increased drought conditions in western Europe and decreased drought conditions in eastern and northern Europe. This pattern was con rmed by Mimikou *et al.* (1999) in their analysis of expected conditions in northern Greece, and they calculated that reductions in mean annual and summer runoff, along with prolonged droughts, would have negative implications for production of hydroelectricity and agricultural crops. Timmerman and White (1997) identi ed other complications for coastal cities, vulnerable to sea level rise due to melting of glaciers driven by higher temperatures. They argued that, in general, coastal cities would be at risk due to sea level rises through increased likelihood of ooding and impeded drainage, salinization of freshwater supplies, higher water tables leading to reduced safety of building foundations, and increased beach erosion.

Regarding the implications of climate change for water resources in the Great Lakes basin of North America, Clamen (1990) highlights the dif culties in forecasting possible implications of changed water regimes due to climate change because of the different ways in which variables are expected to be affected. Thus, overland evapotranspiration, lake evaporation and overlake precipitation were expected to *increase*, soil moisture and ice cover were expected to *decrease*, and snowmelt, runoff, net basin supply and lake levels were expected to *decrease but with an earlier spring peak* (*see* **Water Resources: Great Lakes Case Study**, Volume 3).

What can be concluded is that some regions will have less natural water available to draw upon to meet their needs due to reduced runoff and increased evapotranspiration. Where this condition occurs in a region in which natural supplies are or will become limited relative to demand, then climate change will contribute to greater pressure and stress.

Social Values and Tastes

As Sewell and Bower (1968) have observed, social values and tastes can exert an important in uence on water use and demand, and can either increase or decrease water use. Growing af uence in developed countries often increases water demands, as people are able to give more attention to cleanliness and personal hygiene. As people include one or more daily showers as part of their normal routine and as households add washing machines and dishwashers, water use rises. When households add private swimming pools on their properties, water use increases, as it also does through excessive watering of ower gardens and lawns.

On the other hand, once a stage is reached in which basic needs for water are satis ed, social values and tastes can also shift in a way to reduce water demand. As people become more environmentally sensitive, some will choose to replace lawns and exotic ower gardens with native fauna, which require less water. Others add rockeries or other landscaping features, which require no water.

As with technological changes, it is not easy to anticipate what shifts may occur in social tastes and values, and what their consequences may be for water use. However, any estimates of future water use patterns need to be sensitive to the possible rami cations of changing social values.

Policies

Governments can in uence water use patterns through policies related to pricing for water, metering, and water quality

standards. In many countries, consumers do not pay the full cost for water services, and as a result there is scope to achieve more efficiencies in water use if charging schemes were to be introduced so that consumers paid the total cost for the water received. It is usually believed that full-cost pricing would lead to more careful use by consumers. At the same time, it also is recognized that, until basic needs are met, introduction of full-cost pricing could make access to safe, potable water beyond the reach of the poorest and most vulnerable groups in a society. As a result, issues of effectiveness, efficiency and equity have to balanced in deciding which policies are most appropriate relative to water use.

Sectoral Uses

At a global scale, the largest use of water is for irrigation. Estimates vary, but there is general agreement that irrigation represents almost 70% of water use. Use by industry is second, at about 23%, with domestic and municipal use a distant third at 7%. Over 40% of all withdrawn water is returned to the hydrological system in some form of wastewater. Industry is the source of most of the returned water, since almost 90% of water withdrawn by industry is converted into wastewater. Attention is given to these three uses in this article, since these uses each change the nature of any water returned to the hydrological system for subsequent use by others.

However, it is important to recognize that demands or uses arise from non-consumptive users, such as hydro power generation, navigation and fisheries. The global capacity of all hydro power generating plants in 1970 was 290 gigawatts (GW), which represented 24% of the capacity of all electricity generating plants (conventional thermal, nuclear, hydro electricity, other). By 1984 the capacity was 542 GW, but in terms of total global capacity for electricity generation its share had fallen to 23% due to other types of generating stations being built. By 1988, it was estimated that hydroelectricity generated 7% of total global energy. In contrast, freshwater fish catches grew by a factor of 6 between 1950 and the early 1990s.

CASE STUDY: AGRICULTURE

Temporal Patterns and Trends

Irrigation water use has increased steadily. Rydzewski and bin Abdullah (1992) reported that irrigation agriculture increased from about 8 million hectares (ha) in 1800 to 48 million ha in 1900, and to 94 million ha by 1950. By the early 1990s, it was estimated that irrigation agriculture had expanded to cover 260 million ha, with two thirds of that area in developing countries, and could be expected to continue to increase but at a slower rate because most land suitable for irrigation had already been developed (*see* Irrigation: Environmental Impacts, Volume 3).

Box 2 Reasons for the decline in irrigation investment in Southeast Asia

Contributing factors include the large public and foreign debt loads carried by most of the agriculturally-based economies in the region; the declining share of unexploited irrigation development potential in many countries in the region; and political resistance from environmental interests and those displaced or otherwise negatively affected by irrigation development. However, recent studies show that the main reasons for declining investment are the decline in world rice prices and the increasing real costs per ha of new irrigation development (Svendsen and Rosegrant, 1994).

Given different spatial patterns of irrigation agriculture, it is a challenge to make global generalizations about future water use patterns for irrigation. The experience in Southeast Asia is used here to illustrate possible patterns of future use. Svendsen and Rosegrant (1994) reported that irrigated areas in Asia consisted of about 143 million ha by the early 1990s, which represented about 55% of the total in the world. More than one third of all cropland in Asia was under irrigation by the early 1990s. The steady growth in irrigation agriculture in the region had been due to development of high-yield rice varieties or rice which required heavy inputs of water and agrochemicals to realize their potential. However, in the last decade the rate of creation of new irrigation projects has diminished.

Many reasons accounted for the decline in the establishment of new irrigation areas or expansion of existing projects (Box 2). Certainly one of the key ones was the decline in the price of rice after 1960. By the mid-1990s, the real price for rice was about one third of what it had been in the early 1960s. Thus rice became both more abundant and accessible to lower income groups than at any previous time, and that new irrigation projects to produce more rice became increasingly difficult to justify.

In terms of future patterns of water use for irrigation, Svendsen and Rosegrant (1994) suggested that four factors technology, economic and political liberalization, competition for water and environmental and health concerns would be the most influential. Regarding technology, they believed that adoption of new irrigation technologies in developing countries has been much slower than expected, given the remarkable advances made in such technology in the West over the past 30 years. The explanation, in their view, was that most of the technological advances have occurred with regard to water application rather than conveyance and distribution of water. In Southeast Asia, the normal farm is much smaller than Western farms, but the irrigation development projects have been much larger. As a result, in Southeast Asia, e.g., there

has been little adoption of sprinkler and drip technologies, the focus of research and innovation in the West. Until technological innovations occur with regard to water conveyance, distribution and allocation, there is likely to be little impact of technological change on reducing water use patterns in Southeast Asia. The potential water savings from use of improved technology are considerable, given that Rydzewski and bin Abdullah (1992) have reported that typical efficiency figures for large projects in Asia are 65% for conveyance, 75% for distribution, and 60% for field application, resulting in an overall efficiency of just under 30%. These (in)efficiencies indicate that about 2500 tn of water may have to be diverted into an irrigation system for each tonne of cereal produced.

Economic Liberalization

The factor labeled as *economic liberalization* has been important, and perhaps will be the most important, in influencing development of new irrigation facilities, and therefore future water use needs. Economic liberalization is characterized by market-oriented economic policies, realistic exchange rates, facilitation of international trade, a central role for the private sector in producing goods and services, reduction of subsidies and transparent economic policy instruments. Specific modifications have been made to restrictive policies protecting local producers, keeping domestic prices above world prices or maintaining overvalued exchange rates. Such changes make some industries less competitive at a global scale, relative to agriculture in some nations in Southeast Asia and could create pressure to expand irrigation agriculture and water-intensive manufacturing while internationally uncompetitive industries close or downsize. At the same time, however, given that agricultural exports will have to compete with similar products from other countries, there will be increased incentive to use more water-efficient irrigation in order to reduce production costs, especially if charges for water use are increased under economic liberalization policies. This latter factor could help to reduce the demand for irrigation water use.

Competition for Water

Competition for water can be expected to increase, given that water is a finite resource and that for many purposes no real alternative substitutes exist. Some uses, such as agriculture, will have to compete for water against other higher value commodities, which may make it difficult for the agricultural sector to obtain rights to water needed to support expanded irrigation crop land. In addition, in countries in which priorities are established for water uses, domestic and municipal water use normally is given highest priority, and industrial use second priority, with agricultural water use having even lower priority. In the words of Svendsen and Rosegrant (1994), this situation is likely to result in irrigation agriculture coming under increasing pressure to reduce its consumption and to pay the economic scarcity cost for water rather than the currently highly subsidized rates . When agriculture cannot pay the real cost for water, its rights or allocation may be transferred to other users, as has happened in the American Southwest where higher value users are receiving water once used by agriculture.

Box 3 Predictions regarding irrigation and industrial water use in the future

The use of water for irrigation is bound to grow, but at rates below those experienced in the past century, as most land suitable for irrigation is already in use as such and stricter water pricing will tend to increase water efficiency in agriculture. Industrial water use for processing, cleaning, cooling and removal of wastes, will increase in the next few decades as the economies of developing countries are making the transition to industrialization (Traoré, 1992).

Environmental and Health Concerns

Environmental and health concerns were identified as the fourth force influencing water use patterns. Salinization of irrigated land in arid regions, combined with chemical contamination of surface and groundwater, and rising water tables, are all environmental impacts, which can be associated with irrigation projects. A rising groundwater table can be either positive if it reduces extraction costs for groundwater, and negative if it contributes to secondary salinization of crop land when the groundwater is saline. Many health concerns can emerge, ranging from an increase in waterborne diseases to chemical contamination of domestic water supplies. In addition, the construction of major capital works (dams, reservoirs) to provide water to meet irrigation needs can modify downstream flow regimes, inundate productive cropland, homes and settlements, and destroy or significantly modify habitat which in turn affects biodiversity.

The end result is likely to be that, while irrigation agriculture will remain the single most important water use on a global scale, its importance can be expected to decline relative to industrial, municipal and domestic uses (see Box 3).

In contrast, industrial use of water can be expected to increase, in absolute and relative terms, especially as developing countries industrialize (Table 3). However, as with agriculture, improved water efficiency technologies have the potential to dampen the effects of increasing water use as a result of urbanization and industrialization. Gupta (1992) noted that estimates reveal up to 20% of the initial capital for manufacturing plants in Nigeria has

Table 3 Temporal patterns of water demand (km^3 $year^{-1}$), 1900–2000[a]

Water users	1900	1940	1950	1960	1970	1980	1990	2000

been required to compensate for inadequate supply of urban power and water in that country. Technological improvements could assist to both reduce the amount of water used by the industries and to improve the delivery of water within urban water supply systems.

Municipal and domestic use also can be expected to increase, due to population growth, urbanization, and higher standards of living leading to higher *per capita* use of water. Water use per person varies from 10 35 liters each day in rural areas to 40 to over 300 liters day^{-1} in areas with the highest living standards. Improved water supply systems also could significantly improve health conditions for people in developing countries, which also could contribute to increased productivity. As Gupta (1992) has observed, For the urban poor, water is important for improving their productivity and keeping them in good health. Almost 60% of the deaths amongst the slum settlements in various countries are known to be water-related ••• .

REGIONAL PATTERNS AND TRENDS

Gupta (1992) reported that global water use from 1970 2000 was likely to double, with the North American proportion decreasing from 21 15%. In contrast, the water use needs in Asia were estimated to increase from 58 to over 60% during the same time period. Comparable figures for 1970 and 2000 were 4% and 4% for Africa, 3.3% and 4.2% for South America, and 11% and 13% for Europe.

Regarding domestic water use, the poorest service for safe potable water supplies in 1980, prior to the start of the Water Decade, was provided to the rural poor in the nations of West Africa, with 22% of the population serviced, and in Africa south of the Sahara, where 23% received service. For all of Africa, an average of 30% of the population had access to safe portable water. In contrast, the poorest level of rural sanitation coverage was in Southeast Asia and in the eastern Mediterranean where less than 10% of the population was serviced. These figures translate into global figures of 1.65 billion rural people without access to an adequate supply of safe water supply in 1980, and 1.47 billion rural people without access to good sanitation.

By 1990, Traoré (1992) reported that 1 billion people in developing countries were without access to safe water supply, and some 1.75 billion did not have access to satisfactory sanitation. This need existed, despite the significant progress during the Water Decade (*see* IDWSSD (International Drinking Water Supply and Sanitation Decade), Volume 4). As Traoré (1992) noted, much of this achievement can, however, be accounted for by the major programs having being implemented in China and India, two countries with a major part of the world s rural population. In many of the developing countries less significant progress has been made and conditions are still unsatisfactory with levels of coverage under 20% being not uncommon . On a positive note, most countries in South America have adequate potable water, and indeed Gupta (1992) has stated that South American countries are able to provide about 10 times more water *per capita* than do the countries in Africa and Asia. Tables 4 and 5 provide further insight regarding the spatial patterns of water availability.

In terms of *per capita* water use, the ranges are from as little as 20 liters to over 500 liters. However, only some

Table 4 Water availability *per capita*, mid 1980s

Category	*Per capita* availability	Countries (%)
Very low	1000 m^3 a^{-1} or less	14
Low	1000–5000 m^3 a^{-1}	37
Medium	5000–10 000 m^3 a^{-1}	14

4% of the global population use water in the range of 300 400 liters person^{-1} day^{-1}. In contrast, two thirds of the world s population, located primarily in Africa and Asia, use less than 50 liters daily (Gupta, 1992). It was estimated that by the year 2000 there would be 17% of the global population using more than 300 liters person^{-1} day^{-1}, with the US, Canada and Switzerland having the highest water uses. At the other end of the spectrum, by 2000 it also was believed that 30% of the global population would use fewer than 50 liters daily.

In terms of irrigation agriculture, Rydzewksi and bin Abdullah (1992) concluded that during the period 1950 1980 the annual rate of increase was 4 to 5 million ha. The relative importance of irrigation agriculture varies

Box 4 Forecasts regarding irrigation potential

The forecasts for ultimate potential for irrigated areas in developing countries indicate that it could be as high as double the present figure, i.e., rising to over 300 million ha, but such estimates are usually based only on availability of land and water resources and they become less optimistic when social and economic factors are introduced (Rydzewski and bin Abdullah, 1992).

signi cantly among different world regions. For example, in relation to total irrigatable land at a global scale, irrigation agriculture accounts for 33% in Asia, 21% in Near East/North Africa, 8.5% in Latin America, and 2.7% for Africa. Two countries (China and India) accounted for 40% of the increase in irrigation agriculture between 1950 and 1980, with India being the global leader in terms of irrigation agriculture. Within regions, the importance of irrigated agriculture is even more striking for some countries. Thus, e.g., 100% of agriculture in Egypt is based on irrigation, and Pakistan has 78% of its agriculture land supported by irrigation (see Box 4) (*see* **Irrigation: Environmental Impacts**, Volume 3).

Since 1980 the annual rate of increase of irrigated land fell by about a half, primarily because the best irrigatable land had already been developed and therefore construction costs had increased. In addition, lower commodity prices were a disincentive for farmers in some countries to invest in irrigation infrastructure.

Given the current and anticipated patterns of water use and the ongoing degradation of water sources, it can be expected that there will be regions in the world in which serious scarcity problems will continue to exist. The most obvious trouble spots, in this regard, are the Middle East, North Africa, and various countries in East Asia. Groundwater depletion also is emerging as a problem as it has been documented that groundwater is being extracted at unsustainable rates in many regions of the US, China and India.

ENVIRONMENTAL IMPACTS

Traore (1992) has argued that over wide areas, the degradation of water resources already constitutes the gravest environmental problem, as for instance in several countries in eastern Asia . Contamination of groundwater threatens the safety of water users. For example, in Bangladesh about 97% of the population is dependent on tube well water for drinking and cooking, and it has been established about 40% of Bangladeshis, or 56 million people of the 1999 population of 140 million, was vulnerable to arsenic poisoning from groundwater sources (Naidu and Skinner, 1999).

Four types of environmental impacts from water use are often recognized (Kindler, 1992). First, there may be impacts on or disruption to both human settlement and human activities, as when a dam and reservoir are constructed for water supply purposes, and people have to be relocated from the area, which is inundated by the reservoir waters. Second, developments to meet water use needs can create habitats supportive of parasitic and waterborne diseases (e.g., schistosomiasis, malaria, filariasis and liver fluke infections). Irrigation projects in both humid tropical and arid regions have led to such impacts. Third, there may be physical or chemical impacts, especially as a result of changes in land use or in surface or groundwater regimes. The causal events in this regard normally are the construction of storage reservoirs and flood levees or dykes, designed to control flows of river systems. Fourth, there can be impacts on indigenous flora and fauna.

Expanding use of water for irrigation agriculture illustrates some of the negative environmental impacts, particularly regarding salinization, water logging and contamination of surface and groundwater systems with agrochemicals. Indeed, the success of the Green Revolution has been predicated on the provision of abundant water and the application of fertilizers to achieve higher yields from the new species of rice and other grains. Without sufficient supplies of water, the capacity to grow food from the new hybrid rice to meet the nutritional needs of growing populations will be inadequate.

The Aral Sea basin is a specific example of some of the negative environmental impacts related to irrigation. As Bedford (1996) noted, the Aral Sea basin is plagued by serious environmental degradation, fundamentally related to water use , and has been described variously as a water management disaster, a quiet Chernobyl and the most serious environmental catastrophe of the planet. Most of the negative environmental impacts have been caused by a drive to increase cotton production in the basin through expanding irrigation. Between 1950 and the late 1980s, the area under irrigation increased from 2.9 million to 7.2 million hectares. Specific negative environmental impacts from the massive increase in water withdrawals have included desiccation of the Aral Sea and its delta wetlands, leading to loss of habitat and species, wind-transported salts from the dry Aral Sea bed onto agricultural lands, and alteration of the micro climate. Negative impacts from the application of the withdrawn water onto what often was marginal agricultural land have included the typical arid region problems associated with irrigation of soil salinization and water logging. Increased rates and amounts of use of agrochemicals have led to pollution of food and drinking water supplies. In turn, the ingestion of agrochemicals contained in or on food products has created health problems (*see* Aral Sea, Volume 4).

SOCIAL IMPACTS

Health (Box 5)

Box 5 Irrigation-related diseases

Two of the most important irrigation-associated diseases are malaria and schistosomiasis. [For malaria] ••• the most dramatic effects are seen in arid and semi-arid zones where irrigated agriculture is introduced. However, even in areas which already have a certain level of malaria endemicity, irrigation development may mean a shift from seasonal to perennial transmission with severe consequences especially for children.

Schistosomiasis is a chronic debilitating disease. Many cases of sharp increases in the prevalence rates of this disease from 9% to 70–80% in the wake of irrigation development have been documented, particularly from Africa (Rydzewski and bin Abdullah, 1992).

Despite the Water Decade, the concern about health relative to water use continues to be a critical concern, given that a strong association exists between four diseases or disease groups, and water supply and sanitation. First, as Traoré (1992) has explained, the classical water-borne diseases are cholera and typhoid fever, as well as infectious hepatitis and shigellosis. Even more common, and in the long term much more deadly, are diarrheal diseases associated with poor hygiene and fecal–oral transmission. Second, regarding water-based parasitic diseases, schistosomiasis and dracunculiasis are the most significant. Third, new reservoirs to serve as sources of water for domestic use, irrigation or hydro-power generation affect malaria prevalence. Regarding sanitation, facilities such as pit latrines and sewage drains have contributed to increased incidences of filariasis. Fourth, a major category of water-related disease has emerged, illnesses associated with nitrates, heavy metals, and pesticides.

In terms of future conditions, Traoré (1992) suggested that by the early 1990s it appeared as if diarrhea was causing between four and five million deaths annually in children younger than five years of age in developing nations. Indeed, the World Health Organization (WHO) (1989) estimated that in the first two years of life as many as 15 of 1000 children were dying from diarrhea.

Regional Instability

Scarcity of water, or drought, as demonstrated during the 1970s in the Sahel region of Africa, can lead to significant changes in land cover and land use, and also to the out-migration of residents from the area in which water use needs cannot be satisfied. In such situations, what are increasingly being referred to as environmental refugees migrate to other areas and often need assistance and support. Because the host areas do not provide the basic requirements for potable water and sanitation to the existing domestic population, the arrival of thousands of new

water users can exacerbate an already difficult situation and often lead to social unrest.

Regional instability also can be created when people in a region face chronic rather than acute water shortages. Some people leave the area but most remain. Relative to accepted indicators of well-being, these people subsist and live below the poverty line. However, they also live in what they consider to be their homeland , so are reluctant to migrate away, unless conditions become life-threatening.

It increasingly is being stated that if during the 20th century some regional conflicts and wars were triggered about concerns over access to fossil fuel resources, such conflicts in the 21st century will at least partially be attributable to fair sharing of scarce water supplies. In that context, the most frequently cited region for such potential instability is the Jordan River basin in the Middle East, especially related to access to water on the West Bank. The Israelis, Jordanians and Palestinians all face constraints on economic development due to water shortages, and there are inequities in the way in which water is presently allocated (Ben-Zvi *et al.*, 1998). In the same region, conflicts also exist regarding access to water in Gaza.

Such water conflicts are not hypothetical possibilities. Wolf (1995) referred to the period of 1964 1967 as one of Water Wars , beginning with an Arab decision in 1964 to construct an all-Arab diversion from the Jordan River headwaters which would preclude the operation of the Israeli National Water Carrier (which takes water by pipeline from Lake Kinneret/Galilee in northern Israel southward to the Negev region. In addition, the National Carrier distributes water to other regions, cities, towns and irrigation districts in Israel between Lake Kinneret and the Negev (Kuffner, 1993)). In 1967, Israel used tanks and air strikes to halt construction of the diversion works.

The potential conflicts are not confined to Israel and her Arabic neighbors. During the 1990s, Syria and Iraq each threatened retaliative action against Turkey if that country proceeded to build dams in the headwaters of rivers, especially the Euphrates River, which later flow into their two countries (Turan, 1993; Wakil, 1993). As a result, considerable multilateral effort has been devoted to trying to resolve the allocation of scarce water supplies to meet the water use needs in the Jordan River system (Biswas and Wolf, 1994; Wolf, 1995).

IMPLICATIONS

Distinction Among Different Futures: Probable, Desirable and Feasible

When thinking about future water use demands, estimates of the most probable patterns of water use are compared against estimates of water supplies. When it is concluded that water use will exceed water supplies, then decisions usually are taken to develop new supply capacity so that future water use needs can be met.

However, as highlighted in the discussion regarding the drivers of water use, the preparation of forecasts always involves making many assumptions, ranging from the rate of population growth and urbanization, *per capita* water use, and the nature of the economy, as well changes in technology, climate, social values and tastes and policies. If forecasts related to any of these drivers are faulty, then these become built into the forecasts of future water use patterns, making them also inaccurate.

There is also the issue of focusing on the most probable future, when such future conditions may not be desirable. Indeed, the Water Decade was predicated on the idea that without intervention, the most probable future regarding provision of safe potable water supplies and sanitation services would not lead toward desirable future conditions for billions of people in the world. Thus, it is important that attention be given to both what is likely, and what is desirable. A third consideration requiring attention is what *can* happen. In other words, we also must think about what is a feasible future, as well as what are probable and desirable futures. Society may not always have the human and financial resources to achieve the most ambitious desirable future. For example, some of the goals of the Water Decade were not achieved because time was not taken to train people in villages to maintain pumps and other equipment related to new wells that were dug. As a result, often within a period of one year, the new wells no longer functioned, and the local people had returned to contaminated sources of water.

Role of Sustainability as an Overriding Vision

It is essential to have a sense of desired end point being sought. The word vision often is used to characterize that sense of direction. As Senge (1990) has stated, a vision is a specific destination, a picture of a desired future , and, at its most basic level, answers the question What do we want to create? .

Stewart (1993) has outlined an 8-step process or method to develop a vision, and it is presented here to stimulate thinking about how a vision can be prepared. In his view, the steps should include:

1. developing a comprehensive list of stakeholders and viewing the future state and the present state through their eyes;
2. developing a broad description of the likely future environment;

3. creating a comprehensive vision of what could be, unrelated to existing barriers, before considering the present state;
4. contrasting the future vision with the present situation;
5. identifying the values needed to guide a society or organization as it seeks to realize its vision;
6. ensuring the vision is articulated as actionable concepts;
7. developing the vision in a participatory manner through involvement of stakeholders; and,
8. avoiding development of a strategy or taking action until the vision and values have been established.

The distinctive features of Stewart s approach are that a conscious decision is taken to separate the characteristics of the desirable future state with the pathway or process to reach it, and to first focus on the future before assessing the present situation.

Sustainability, or sustainable development, has been held out by many as a desirable vision or endpoint for water management (Young *et al.*, 1994). In that context, emphasis has been placed on meeting the needs of people today, while ensuring that the needs of future generations also will be met. As the World Commission on Environment and Development (WCED) (1987) explained, sustainable development as a vision contained the key concept of ••• needs, in particular the essential needs of the world s poor, to which overriding priority should be given . The Water Decade focused on meeting the demands of the World s poorest people regarding basic water use needs, and this should continue to be a global priority. A World Water Commission has been established, and one of its first priorities has been to develop a global vision for water (Serageldin, 2000).

Role of Supply and Demand Management to Meet Needs

The conventional approach to meeting water use needs has been to expand existing sources, or to create new sources. Thus, if water use was expected to exceed supply capacity, the usual approach has been to build another water supply reservoir, construct a pipeline to a lake or similar source, or drill a deeper or new borehole or well. This approach has been labeled as the *supply management approach*, since the emphasis has been upon enhancing or increasing the supply of water. The key component of the supply approach has been structural, or building new water supply facilities.

One of most promising supply management options is desalinization. Dziegielewski (2000) reported that in 1962 the energy requirement to desalinate 1000 gallons of water was 100 kilowatt-hours (kWh), or 26.4 k Wh m$^{\bullet 3}$ whereas by 1998 this requirement had decreased to 11 k Wh 1000$^{\bullet 1}$ gallons or 2.9 k Wh m$^{\bullet 3}$. This reduction in energy requirements is primarily due to the invention of reverse osmosis. In the US, the cost of desalinated water in 1999 was about \$11 000 gallons$^{\bullet 1}$, making it competitive with the cost of importing water into many urban areas. Thus, desalinization is no longer significantly more expensive, as it used to be when contrasted to the historical cost of developing new water supplies. Indeed, the cost of desalinated water continues to decrease, whereas the cost of water from other sources is generally increasing. In Tampa Bay, Florida, the decision was taken to build a 25 million gallons per day desalinization plant which will be completed in 2002 and will provide 10% of the total water supply capacity. This option was chosen because of the environmental impacts (groundwater overdraft and over pumping of lakes) associated with an alternative project to withdraw additional freshwater.

As the most suitable dam and reservoir sites became developed, and as awareness grew about some of the negative environmental and social impacts of major structural works, attention has turned increasingly to what has been labeled as a demand management approach. In this approach, the focus shifts away from providing additional water supplies to meet anticipated use and toward modifying human behavior, and especially to reduce wasteful use of water resources (Shrubsole and Tate, 1994). In situations in which basic human needs already are satisfied, the *demand management approach* is appropriate. Through various pricing schemes and regulations on activities such as watering of gardens and lawns, it is possible to reduce peak demands, which require water supply capacity only used for a small part of the year, and also to reduce overall levels of use. However, in situations in which basic human needs are not met, increasing the price of water, so that consumers pay the total cost of providing it to them, has the potential to make safe drinking water inaccessible to the poorest and most vulnerable people in a society. As a result, caution has to be taken in using some of the tools in the demand management approach, notwithstanding that in most developed countries there is considerable scope to achieve efficiencies in water use patterns, and to reduce waste.

It has never been suggested that the demand management approach should replace the supply management approach. Instead, the argument usually has been that water managers have over-relied on the supply management approach, usually because the key decision makers have been civil engineers, whose training emphasized building things to fix problems, whether they be water, energy or transportation. The emerging view is that supply and demand management approaches should and can be used together, to develop a package custom-designed for any given situation. This view is an appropriate one, and over-reliance on the supply management approach must steadily give way to a more balanced and combined approach in which both supply and demand management methods are used.

Contaminated Lands and Sediments: Chemical Time Bombs?

WILLIAM M STIGLIANI

Center for Energy and Environmental Education, University of Northern Iowa, Cedar Falls, IA, USA

In 1988, investigators reported a trend of increasing mercury content in sh in Swedish lakes, even though there had been a signi cant decrease in mercury emissions from Swedish industries in the previous two decades (Hakanson et al.*, 1988). Commenting on this trend, the authors noted that " old Swedish 'sins' are still causing a lot of problems" . In the 1990s, the addition of phosphate (PO_4^{-3}) fertilizer to fruit orchards in Washington State caused the fruits to become contaminated with arsenic, even though the application of lead arsenate (AsO_4^{-3}) insecticides was discontinued in 1947 (Creger and Peryea, 1994; Peryea, 1991). Today in regions such as the Great Lakes of North America, infants exposed in the womb to dichloro-diphenyl-trichloroethane (DDT) and polychlorinated biphenyls (PCBs) suffer developmental and learning disorders, although these chemicals have been banned or severely restricted since the 1970s (National Research Council, 1999).*

Such occurrences suggest that: (1) environmental effects may be displaced in time from the activities that cause them; and (2) even when reductions in polluting emissions are enacted, environmental effects may still occur owing to the accumulation of polluting materials in the environment over previous decades. Policy makers and the public alike may be surprised by the onset of such observed deterioration in the environment, since prevailing wisdom might suggest that an era of lowered emissions of pollutants to the environment should be accompanied by an improvement in its state, rather than a worsening.

While regulators have focused their attention on highly contaminated waste sites and the means by which to mitigate acute threats to the public, they have largely ignored the potential impacts from the slow accumulation of toxic materials in soils and sediments over the long term. From a public policy viewpoint, this lack of regard supports the assertion by Brooks (1986) that the manifestation of economic bene ts and environmental costs may characteristically differ in two important respects. First, whereas the bene ts of activities that pollute the biosphere are directly proportional to the scale (higher production and use produces more wealth), the environmental costs may vary nonlinearly with scale. Second, bene ts are typically manifested on fast time scales, while the costs become obvious on relatively slow time scales. This mismatch of time scales can be problematic because a technological activity with all its obvious bene ts may become strongly entrenched, and thus dif cult to scale back, before its true environmental costs are known.

DETOXIFICATION AND RETOXIFICATION OF THE BIOSPHERE

As conceptualized by Salomons (1995), one may visualize the transport of heavy metals in the environment as a wheel in which the metal moves with relentless progression from the hub to the periphery (left side of Figure 1). Heavy metals released to the air or aqueous (aq.) systems (center and inner circle of the wheel, respectively) are transferred to soils and sediments (outer circle). The lifetimes of metals in air are on the order of days, and in water they are months to years. In contrast, the residence times of heavy metals in soils and freshwater and estuarine sediments can be much longer, on the order of decades to centuries or more. Eventually, through erosion and resuspension processes the metals are transferred from the land to marine and deep ocean sediments, their ultimate sink. One may view this transport as a natural detoxification process by which air, soils, freshwaters and their sediments purge themselves of pollutants and transfer them for burial, and out of harm s way, in the sediments of the deep oceans. This voyage, however, from the terrestrial biosphere to deposition in ocean sediments, can take thousands of years or longer. The cycle is renewed though crustal uplifting when ocean sediments are transformed into new landforms, but this process takes millions of years. Hence, on time scales

important to human concerns, soils and freshwater and estuarine sediments can be viewed as the ultimate sinks for heavy metals. Typically, well under 1% of the metals released to the environment reside in air and water. The remainder accumulates in soils and sediments. Persistent organic compounds such as DDT and PCBs are another class of harmful chemicals that accumulate in soils and sediments, and are discussed later in this article.

Important sources of heavy metals to the environment are direct industrial discharges, atmospheric deposition, corrosion of building materials and traffic related emissions in urban areas, erosion and storm runoff from agricultural soils and paved urban areas, and leaks from municipal landfills and toxic waste dumps. Emissions from these sources may be in accordance with regulatory standards, and stem from common anthropogenic activities not normally considered as important sources of soil and sediment pollution. The point to stress, however, is that while such sources may add small incremental increases to the environment on an annual basis, their cumulative load integrated over many decades can be substantial (*see* Anthropogenic Metabolism and Environmental Legacies, Volume 3).

It is not total accumulation of a heavy metal in a soil or sediment that is important, but rather its bioavailability. Bioavailability is mostly determined by the water soluble fraction of the accumulated chemical in soil water solution or in pore water in sediments; the adsorbed, insoluble phase is not available for biological uptake. In relatively unpolluted soils and sediments, the soluble phase is typically only a small fraction of total accumulation. The question raised here and illustrated on the right side of Figure 1 is whether, and under what conditions, soils and sediments serving as sinks for toxic heavy metals can reverse their role and become important sources of heavy metal pollution in drinking water, crops and vegetation, and aquatic and terrestrial wildlife? We may think of such a reversal as a retoxification process in the biosphere.

THE CHEMICAL TIME BOMB CONCEPT

The chemical time bomb (CTB) concept addresses the varied mechanisms by which retoxification may occur. It was originally formulated by Stigliani (1988), and resulted in a five-year collaborative effort between the International Institute for Applied Systems Analysis (IIASA) in Laxenburg, Austria, the National Institute of Public Health and Environmental Protection in Bilthoven, the Netherlands, and the Netherlands Ministry of Housing, Physical Planning and Environment. The findings of the ensuing studies are provided in Stigliani (1996), Salomons and Stigliani (1995), Stigliani and Anderberg (1994), Stigliani and Salomons (1993), ter Meulen *et al.* (1993), Hesterberg *et al.* (1992), Stigliani (1991), and Stigliani *et al.* (1991).

A CTB is defined as an unforeseen chain of events resulting in the delayed and sudden occurrence of harmful effects due to the mobilization or chemical transformation of chemicals stored in soils and sediments in response to saturation or alteration in certain environmental conditions (adapted from Stigliani *et al.*, 1991). The idea of chemical saturation of stored pollutants in soils is illustrated in Figure 2(a). It shows that an added pollutant is partitioned between an adsorbed (sorbed) solid state (Q) and a dissolved aq. state (C). At an early stage, most of the pollutant remains in the sorbed phase, illustrated by the large value of the ratio of $\Delta Q_1/\Delta C_1$. As pollution continues over time, the ratio of the sorbed to mobile pollutant diminishes, as shown by the lower value of $\Delta Q_2/\Delta C_2$. Thus, a pollutant added at a constant rate over time will cause the fraction that goes into solution to become larger and larger. The figure also shows a maximum soil sorption capacity . This is the point at which virtually all of the input pollutant goes to the soluble phase because the soil is saturated with respect to its ability to adsorb it.

A second mode of saturation is illustrated in Figure 2(b). This mechanism involves a change in a soil property that

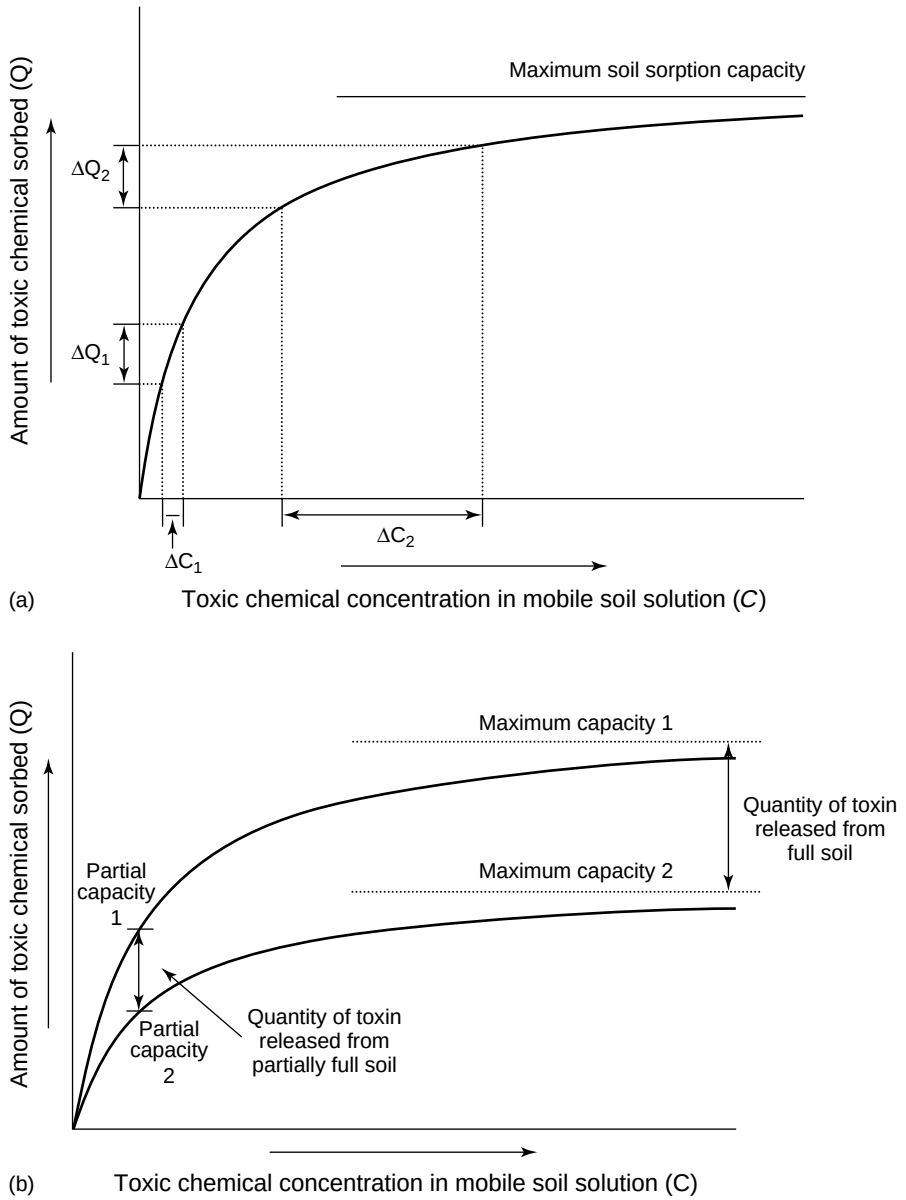

Figure 2 (a) Partitioning of a toxic chemical between its sorbed (Q) and soluble (C) states; (b) effect of changing soil or sediment properties on mobilizing a stored toxic chemical. (Reproduced from Hesterberg *et al.*, 1992)

reduces the maximum capacity from state 1 to state 2. When this occurs, a significant fraction of the sorbed chemical from state 1 (indicated by partial capacity 1 on the upper curve in the figure) is desorbed as the system reaches a new equilibrium defined by state 2 (indicated by partial capacity 2 on the lower curve in the figure). Reaching saturation in soils with high initial sorption capacities (Figure 2a) can take a long time. However, saturation can occur quickly and unexpectedly via the process indicated by Figure 2(b).

To illustrate how the second mode operates, consider the example, cited above, of arsenic contamination of fruit orchards in Washington State. Acid lead arsenate ($PbHAsO_4$) was the preferred pesticide for insect control in deciduous fruit trees before the introduction of DDT in 1947. Frequent high rate applications led to substantial lead and arsenic accumulation in orchard topsoils. AsO_4^{-3} adsorbed to the surfaces of soil particles through ligand exchange with hydroxides (OH^-), hydrous metal oxide minerals (iron/magnesium oxides), phyllosilicate clays, and soil carbonates. In recent decades, fruit growers began applying PO_4^{-3} fertilizer to their orchards to increase yield. This had the unexpected result of mobilizing AsO_4^{-3} with subsequent uptake through the roots and into the fruit. PO_4^{-3} additions mobilized AsO_4^{-3} because it adsorbs more

tightly to soil surfaces, i.e.;

$$\{\text{soil particle surface}\} - AsO_4^{-3} + PO_4^{-3}(\text{aq.}) \longrightarrow$$
$$\{\text{soil particle surface}\} - PO_4^{-3} + AsO_4^{-3}(\text{aq.})$$

Thus, PO_4^{-3} in the aq. phase replaces adsorbed AsO_4^{-3} on the surface of the soil, rendering the AsO_4^{-3} soluble and available for plant uptake.

The mechanism at play here was a rather rapid reduction in the soil s initial capacity to adsorb AsO_4^{-3} and keep it safely locked in the soil. Referring to Figure 2(b), the soil was in a partially full state (marked by partial capacity 1). Addition of PO_4^{-3} effectively shrank the capacity of the soil to adsorb AsO_4^{-3} by taking over the sites at the soil surfaces that had been occupied by AsO_4^{-3}. A new equilibrium was established between sorption and solubility as indicated by the curve marked by maximum capacity 2 . To reach this new stage, the soil released sorbed AsO_4^{-3} to the soluble phase (in an amount marked by the arrow between partial capacity 1 to partial capacity 2) that became available for plant uptake.

With respect to heavy metals, six soil/sediment parameters are particularly important in causing the type of shift shown in Figure 2(b). These parameters, dubbed Capacity Controlling Parameters (CCPs), are given in Table 1.

Thus, reducing the load of mobilizable heavy metals in the biosphere depends not only on reducing the input loads, but also on controlling human activities that tend to affect CCPs. As noted in Table 2 these include land use and intensity of land use, energy production, and the numerous activities that contribute to climate change. It is particularly noteworthy that climate change may be expected to affect all the CCPs to some degree.

Table 1 Important soil/sediment capacity-controlling properties (CCPs) for heavy metals

CCP	Detrimental environmental effect
CEC[a]	Soils with low CECs have correspondingly low capacities to retain heavy metals by sorption; CEC depends on inorganic clay mineral content and type, organic matter content, and soil pH
pH	Lowering pH increases heavy metal solubility, decreases CEC, and alters soil microbial populations
Eh[b]	Decreasing redox potential (*see* **Redox Potential**, Volume 2) dissolves iron and manganese oxides, resulting in the mobilization of sorbed toxic chemicals; in Hg contaminated sediments under low Eh, bacteria can generate highly toxic methylmercury; increasing redox potential mobilizes heavy metals by dissolving insoluble metal sulfides
OM[c] content	Decreasing OM content reduces CEC, soil pH, buffering capacity, sorption capacity for toxic organics, soil water-holding capacity; alters physical structure (e.g., increases soil erodibility), and decreases microbial activity
Salinity	Increasing salinity solubilizes toxic chemicals by altering the ion exchange equilibrium, increasing soluble complexation, and decreasing chemical thermodynamic activities in solution; it can also decrease microbial activity
Microbial activity	Altering microbial activity can affect other CCPs including organic matter, redox potential, pH; sulfate-reducing bacteria synthesize and emit methylmercury

pH AS A CAPACITY-CONTROLLING PROPERTY IN SOILS

Acid Buffering Domains in Soils

Ulrich (1983, 1981) has classified the dominant buffering reactions in soils into four distinct ranges (*see* Buffering Capacity, Volume 2). These are shown in Table 3.

Table 2 Linkages between human activities and changes in CCPs

CCP	Human activities affecting CCP
CEC	Affected indirectly by activities that affect pH, organic matter, and salinity
pH	Atmospheric acid deposition from coal combustion; agricultural practices (liming increases pH, nitrogen fertilizer decreases pH); deforestation decreases pH; climate change altering the nitrogen cycle, and the seasonal patterns of precipitation and evapotranspiration
Eh	Drainage of wetlands or flooding of dry lands either as deliberate land use policy, or as a consequence of climate change
OM content	Deforestation decreases OM; changes in vegetation; agricultural practices (recycling crop residues and manure increases OM, intensive, high input farming without recycling decreases organic matter); climate change can increase or decrease OM
Salinity	Irrigation with salty ground waters; salt water intrusion of ground waters due to sea level rise
Microbial activity	Affected indirectly by activities that affect redox potential and pH, and directly by synergistic effects of multiple toxins, and climate change

Table 3 Buffering ranges in soil solution

Type	Range
Carbonate	$pH \geq 6.2$
Cation exchange	$4.2 \leq pH < 6.2$
Aluminum	$3.8 \leq pH < 4.2$
Iron	$pH < 3.8$

Source: Ulrich (1983, 1981).

Carbonate solids are efficient buffers in the neutral to basic range ($pH \geq 6.2$). Addition of acid in the soil causes the dissolution of solid carbonate and neutralization by the following reaction:

$$MCO_3 + 2H^+ \longrightarrow M^{+2} + H_2CO_3 (M = \text{Ca and/or Mg})$$

When the carbonate solids are distributed in sufficiently fine particles or grain coatings and evenly dispersed in the soil horizon (calcareous soils), the buffering capacity is nearly inexhaustible for any reasonable level of acid inputs.

If carbonate solids are depleted or absent from the soil, the buffering processes are controlled by cation exchange on aluminosilicate clays, a dominant soil type in temperate zones of the world. Clay soil particles possess negative charges on their surfaces that govern the balance between accumulation and solubilization of positively charged ions (cations) present in soil water solution. The number of negative sites available for a given volume of soil depends on soil type, and is measured by the CEC. Soil organic matter also contributes significant CEC owing to the presence in its structure of negative charges originating from phenolic ($-OH$) and organic acid ($-COOH$) constituents. These negative sites attract cations (C^+) that adsorb on the surface of the particle (see Figure 3a). The common natural cations found in abundance in clay soils are the four so-called base cations that include sodium (Na^+), potassium (K^+), magnesium (Mg^{+2}), and calcium (Ca^{+2}). These cations serve two essential roles: (1) they are nutrients for plant and animal life; and, (2) they buffer the acidity of soil solutions. As shown in Figure 3(a), hydrogen ions (H^+) in soil water take the place of base cations at the negatively charged surface sites. This step renders the solubilized base cation bioavailable, while at the same time reducing the soil water s acidity. The exchange is efficient because H^+ adsorbs more strongly to the charged clay site than the base cations. In general, cations are held and displace one another in the sequence:

$$Al^{+3} > H^+ > Ca^{+2} > Mg^{+2} > K^+ > NH_4^+ > Na^+$$

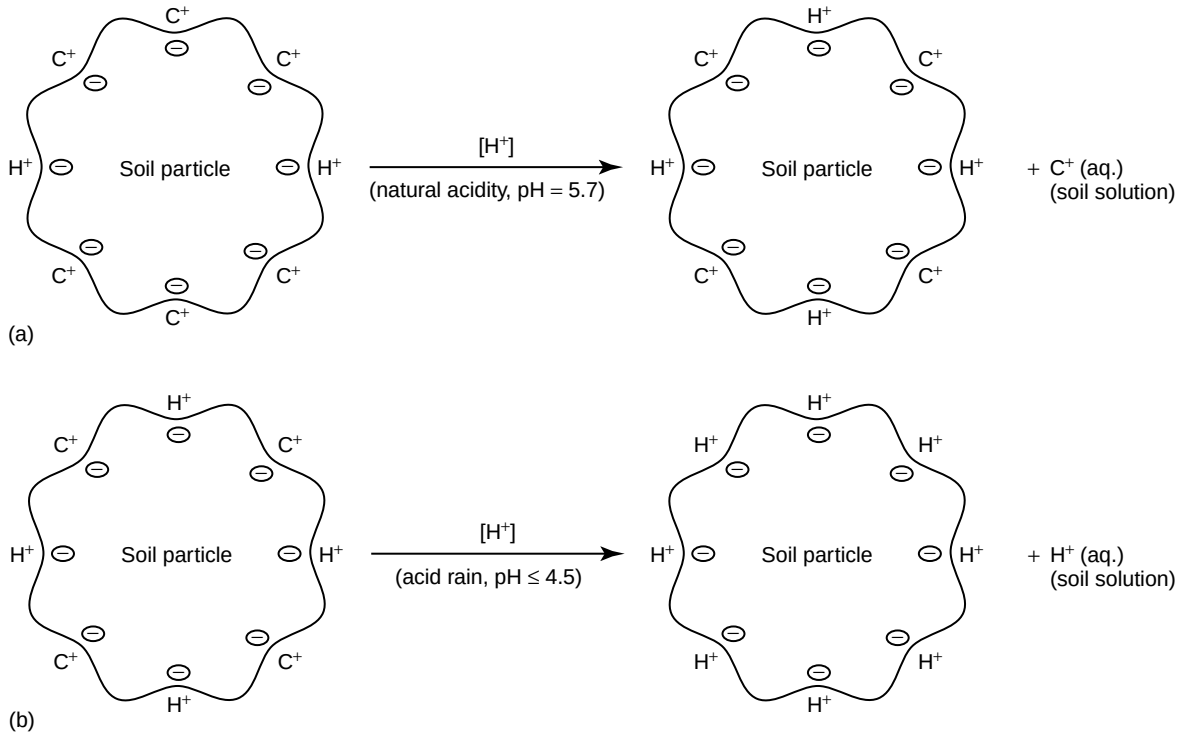

Figure 3 (a) Natural exchange between hydrogen ion (H^+) and a base cation (C^+) in a clay soil with high base saturation (β); (b) exchange between H^+ and C^+ in a clay soil subjected to acid rain

Unpolluted rainfall that drains through clay soils is naturally acidic (pH = 5.7), so the exchange shown in Figure 3(a) is an important step in the cycling of nutrients in the biosphere. Problems arise when polluted rainfall (so-called acid rain with pHs typically 4.5 or lower) percolates through clay soils. As illustrated in Figure 3(b), in this case H^+ is so concentrated that it sweeps away most of the base cations, leaving few additional surface sites available for H^+/base cation exchange. At this point, the clay has reached its saturation point with respect to its ability to buffer the acidic soil solution water, and runoff from these soils contains acid (H^+) rather than base cations. When such soils lie within the watershed of a lake, the unbuffered surface and subsurface runoff causes lake acidi cation.

Soil scientists use the parameter base saturation, signi ed by β, to describe the percentage of exchange sites that are occupied by base cations. For example, a clay soil with a β value of 100% has all of its negative sites occupied by base cations; values of 50 and 0% have one half and none of the sites occupied, respectively. In practice when the value of β declines to about 5%, the soil has essentially lost its ability to buffer acids. The buffering capacity at any given time equals $\beta \times$ CEC.

Soils continually replenish the base cation supply through weathering of bedrock. The supply of base cations as a component of soil (the exchangeable pool) is typically minuscule compared to the total pool that is locked in the parent rock (primary and secondary aluminosilicate minerals). While the exchangeable pool reacts rapidly with soil solution, the pool of base cations contained in mineral rocks is released relatively slowly, owing to the resistance of the parent rock to decomposition and dissolution. Weathering rates vary greatly for different soil types. The most acid-sensitive soils produce enough base cations to neutralize only 0.02 to 0.05 grams of H^+ per square meter per year ($g\,m^{-2}\,year^{-1}$). In areas highly impacted by acid rain, for example Central Europe in the early 1980s, H^+ deposition rates as high as $0.60\,g\,m^{-2}\,year^{-1}$ have been measured.

At the lower end of the cation exchange buffering range (when β declines to approximately 5% and the pH hovers around 4.2), sulfate, the typical anion associated with acid rain, is immobilized as aluminum hydroxysulfate. If sulfate is the only strong acid anion present, the soils do not acidify any further. On the other hand, the presence of another strong acid anion such as nitrate will promote the onset of the aluminum buffering regime, which operates over the pH range from about 4.2 down to 3.8. Nitrate is a common component of acidic deposition and is also generated in natural biochemical processes. Moreover, it cannot be immobilized, except by plant uptake. Thus, when the rate of nitrate inputs to the soil exceeds the rate of plant uptake, aluminum becomes the dominant buffer.

The reaction governing aluminum buffering is:

$$Al(OH)_3(solid) + 3H^+ \rightleftharpoons Al^{+3}(aq.) + 3H_2O$$

At pHs above 4.2, the equilibrium is shifted to the left in the above equation, rendering aluminum mostly in the insoluble form of $Al(OH)_3$. Under strongly acidic conditions below pH = 4.2, the equilibrium is shifted to the right, causing neutralization of H^+ and dissolution of $Al(OH)_3$ to soluble Al^{+3}. Unlike the neutralization reactions in the cation exchange buffering range that generate dissolution of the bene cial base cations, Al^{+3} is extremely toxic. Releases of soluble Al^{+3} from forest soils have been documented in the northeastern US (Johnson *et al.*, 1981), and in Central Europe (Schulze, 1989). Since aluminum compounds are abundant in clay soils, buffer capacity in this range is rarely depleted.

The iron buffer range occurs only at an extreme stage of acidi cation soil solutions with pHs lower than 3.8. Its mechanism is similar to that of aluminum; H^+ is neutralized by dissolution of iron oxides. Soils in this extreme pH range often cannot support fauna and ora because they leach heavy metals and nutrients.

In summary, Figure 4 shows the progression of soil acidi cation that may occur as the buffering regime shifts from carbonate buffering to cation exchange buffering (at time t_1), and nally to aluminum buffering (at time t_2). The pace at which acidi cation occurs varies greatly, depending on both the rate of acidic inputs and speci c soil properties. Calcareous soils may never become acidi ed, but poorly buffered soils on slow weathering siliceous bedrock may acidify quickly.

The Acidification of Big Moose Lake: a Practical Example

The above discussion suggests that the process of reducing a soil s buffering capacity is not instantaneous, but rather occurs over time scales that vary widely, depending upon values of CEC, β, and the base cation replenishment rate, as well as on the rate of input of the pollutant to the soil. Very few studies are available that have monitored the progression of a soil from its natural, unpolluted state up until its loss of ability to buffer acidic inputs. The acidi cation of Big Moose Lake, shown in Figure 5, is one case where such information is available (Stigliani, 1988). The gure shows historical trends in pH, upwind emissions of SO_2, and sh extinctions. Emissions of SO_2, generated mostly by the burning of coal, are relevant because this molecule is converted to sulfuric acid (H_2SO_4) in the atmosphere. It is the dominant ingredient of acid rain globally, although nitric acid (HNO_3) plays a major role as well. The lake is situated in the Adirondack Mountains of New York State. The soils in this region possess relatively low buffering capacities, and, positioned downwind from western Pennsylvania

and the Ohio River Valley, the old industrial heartland of the US, they have experienced among the highest levels of acid deposition in North America (approximately 2.5 grams of sulfur and 0.14 grams of H^+ per square meter per year in the first half of the 20th century).

One may observe that the pH of the lake remained essentially constant at around 5.6 (except for a slight decline due to natural senescence) over the entire period from 1760 to 1950. Then, within the space of 30 years (1950 to 1980), the pH declined more than one whole pH unit down to about 4.5. Interestingly, the onset of the pH decline was not synchronous with the onset of sulfur emissions. Rather, it occurred 70 years after the beginning of SO_2 emissions, and 30 years after the emissions peaked at between three and four million tons of sulfur per year. Apparently, it required this amount of time for the acid inputs to deplete the buffering capacities of the soils in Big Moose Lake s watershed. Thus, beginning around 1950 atmospheric acid deposition

moved through the buffer-depleted soils and percolated into the lake with little or no neutralization. At that point, acid-sensitive fish species such as smallmouth bass, whitefish, and longnose sucker progressively disappeared, followed in the late 1960s by the more acid-resistant lake trout.

From a chemical point of view, one may infer from the shape of the historical pH curve that Big Moose Lake was the subject of an inadvertent titration experiment conducted over four generations of industrial activity. The coal-driven industrialization of the Ohio Valley supplied the acid inputs (mostly as H_2SO_4 formed from SO_2 released during coal combustion), and the soils of the watershed provided the supply of buffering chemicals. The watershed s natural buffering capacity delayed the deleterious environmental effects of coal burning for nearly a century.

Effect of Acidification on Soils Contaminated with Toxic Heavy Metals

Although acidification of soils and freshwaters is, in and of itself, deleterious to biota, the effect is magnified when soils are polluted by toxic heavy metals such as cadmium, copper, nickel, lead, and zinc. As cations, these metals compete with hydrogen and the base cations for cation exchange sites in clay soils. Under conditions of high pH, heavy metals in well-buffered soils are generally retained at the exchange sites, and the concentrations in soil solution are low. But, as illustrated in Figure 6 for the case of cadmium (Cd), mobilization measured as the leaching velocity increases by more than an order of magnitude as the pH declines from 7 to 4. (*Leaching velocity* is the rate at which dissolved cadmium would leach through a soil under standard rainfall conditions in the Rhine Basin. But cadmium in its dissolved form is equally likely to be taken up by crops. Thus, leaching velocity is an indicator of the metal s bioavailability.)

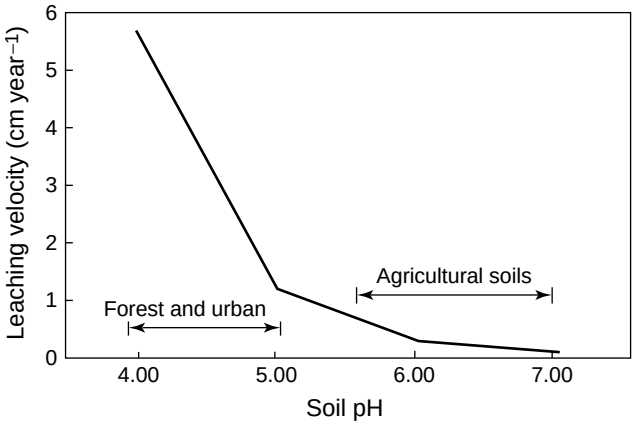

Figure 6 Leaching velocity of cadmium as a function of soil pH. (*Source:* P R Jaffe and W M Stigliani (1993) personal communication, International Institute for Applied Systems Analysis (IIASA), Laxenburg, Austria)

Therefore, at near-neutral pHs the soil will tend to store and accumulate cadmium. As the soil acidifies, H^+ increasingly replaces Cd^{+2} at the exchange sites, and the concentration of Cd^{+2} increases in soil solution. Once in the aq. phase, the cadmium is mobilized and biologically active. It is either transported downward to deeper soil horizons and groundwater (if the groundwater table is high), or taken up by vegetation.

Apart from clays, other common soil minerals are efficient adsorbers of heavy metals. Among the most important are the iron oxides (hematite, maghemite, magnetite) and oxyhydroxides (ferrihydrite, goethite, akaganeite, lepidocrocite, feroxyhite), and the manganese oxides (phyllomanganates, birnessite group of minerals).

The impact of pH, iron and manganese oxides, carbonate, and redox potential (Eh) on bioavailability and human health is obvious from Table 4, which compares cadmium contamination in two disparate regions. Shipham, England was the site of zinc mining from the 16th to the 19th centuries. In the Jinzu region, Japan some relatively minor silver and lead mining occurred in the 16th century, but activities greatly escalated in 1905 when a large zinc refining plant came into operation, generating high tonnages of wastes that were routinely dumped into the Jinzu River. Since cadmium is present in trace amounts (up to a few percent) in virtually all zinc ores, zinc mining and refining are almost always associated with cadmium pollution.

Cadmium in the Jinzu soils was more mobile (and thus more bioavailable) than cadmium in the Shipham soils owing to differences in CCPs (see Tables 1 and 4). The lower pH in Jinzu soils reduced their capacity to adsorb and immobilize the cadmium (H^+ bonds more strongly to soil adsorption sites than Cd^{+2}). Both high pH and high concentrations of manganese/iron oxides (which, as noted above, are particularly effective adsorbers of heavy metal cations such as Cd^{+2}) enhanced adsorption of cadmium in the Shipham soils. The difference in redox potential was another important factor. The submerged soils in the

Table 4 Impact of cadmium pollution on human health: a comparison of two regions

Soil parameter	Shipham, England	Jinzu, Japan
Maximum soil Cd concentration	>300 ppm[a]	70 ppm[a]
Soil pH	7.5	5.1
$CaCO_3$ concentration	6–14%	0.4%
Mn/Fe oxide concentration	High	Low

rice paddy fields provided a low redox environment under which the manganese/iron oxides were reduced to the soluble ions Mn^{+2} and Fe^{+2}. These chemical forms are incapable of adsorbing heavy metals, and, in any case, as soluble ions they are removed from the soils by rapid leaching.

Thus, even though soil cadmium levels exceeded 300 ppm (a thousand times higher than typical rural levels) at the English site, the soil conditions rendered most of the cadmium unavailable for crop uptake. Consequently, health inventories of inhabitants ingesting food grown in this area showed only slight effects attributable to cadmium (Morgan and Simms, 1998). In contrast, soils in the Jinzu region, with cadmium levels much lower at 70 ppm, favored the mobilization of cadmium and uptake into the rice. This resulted in the world s worst episode of cadmium poisoning, in which hundreds of persons became seriously ill from eating rice contaminated by polluted river water used for irrigation (Nogawa *et al.*, 1999).

Are there other similar disasters waiting to happen, and if so, how can they be identified? In order to forecast where heavy metal pollution may occur, two indicators are: 1) areas where high loads of heavy metals are accumulating; and 2) areas where changes in soil/sediment factors (CCPs) could plausibly occur.

Example of Agriculture in the Basin of the Rhine River

Agricultural lands of Europe s Rhine Basin provide one example of an area where toxic metals have accumulated (Stigliani and Anderberg, 1994; Stigliani *et al.*, 1993). This area, comprising about 10 million hectares, is among the most intensively cropped land in the world with a history of exceedingly high agrochemical inputs. One of the major sources of cadmium pollution in the basin has been PO_4^{-3} fertilizer. Like zinc, PO_4^{-3} ores carry cadmium as a trace impurity, and it is retained in the nished fertilizer product. PO_4^{-3} additions to cropland added an estimated 2100 tons of cadmium to the Rhine Basin soils between 1950 and 2000. Moreover, the basin is one of the most highly industrialized regions in the world with a long history of industrialization. Atmospheric emissions from iron and steel manufacturing, non-ferrous metal re ning, coal combustion, and municipal waste incineration have contributed large amounts of cadmium to soils via atmospheric deposition, estimated at about 2400 tons over the same 50 year period.

Figure 7 shows the estimated net buildup of average cadmium concentrations in the basin s agricultural soils, suggesting an overall doubling from around 350 g hectare^{-1} in 1950 to about 750 g hectare^{-1} in 2000. One obvious concern is whether the doubling in concentration poses health risks to humans eating food grown in the basin. The question is complex because, as emphasized in the earlier discussion, the mobilizable fraction of cadmium taken up by the crop will be less than the total amount present in the root zone of the soil.

Numerous publications have indicated soil pH is a major factor controlling both the total and relative crop uptake of cadmium (Kabata-Pendias, 2001). A sensitivity analysis was conducted to determine how plant uptake might change with changes in soil pH. The results are provided in Figure 8, which include the in uences of both changing pH

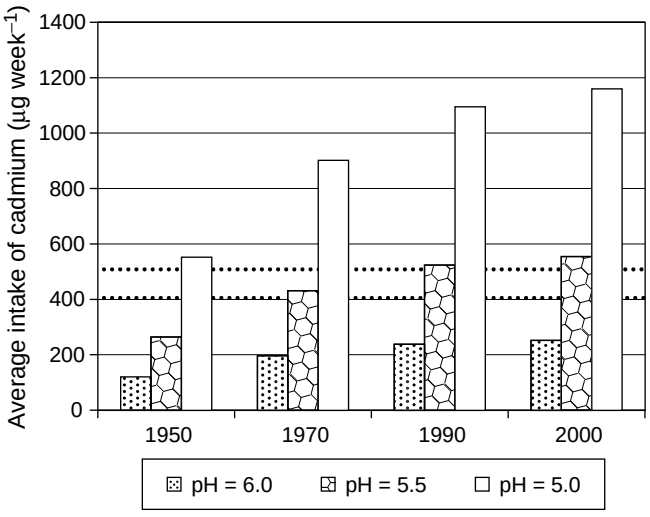

Figure 8 Estimated average dietary intake of cadmium from crops grown in the Rhine Basin as a function of time and changes in soil pH. It is assumed that the total food intake is from crops grown in the basin. Dotted horizontal bar refers to weekly limits of cadmium ingestion defined by the World Health Organization (WHO). (Reproduced from Stigliani and Jaffe, 1993)

and increasing concentrations of soil cadmium over time. Also in the figure is the recommended ingestion limit established by the WHO of 400 500 μg cadmium per week. The baseline of comparison is set at pH = 6.0. This corresponds to a typical pH in a well-limed soil. Holding this pH constant over time, the model estimates that in 1950 a person whose diet included only food grown in the basin ingested about 120 μg cadmium per week, rising to about 250 μg week^{-1} in 2000. Both of these values are well below the WHO limit. If cadmium inputs were to remain constant at the 2000 level, it would take about 100 years for the ingestion rate to reach 400 μg week^{-1}, and 1500 years if the cadmium were removed from the applied PO_4^{-3} fertilizer. Thus, it would appear, over the short term, that cadmium toxicity does not pose a serious threat to those consuming food grown in the basin.

On the other hand, the figure shows that even small declines in the soil s pH would cause relatively large increases in crop uptake. A decrease of just one-half a pH unit to 5.5 in 2000 would increase the cadmium intake to greater than 550 μg week^{-1}, and a decrease of one pH unit to 5.0 would increase cadmium consumption to over 1150 μg week^{-1}. It is noteworthy that in 1950 a one-half unit decrease in pH would not have caused intake to exceed the WHO standard. Even a one whole unit decrease to pH = 5.0 would have just barely exceeded the intake standard (to 552 μg week^{-1}). Thus, the overall effect of the creeping accumulation of cadmium has been to diminish the margin of safety with respect to enhanced crop uptake with declining pH. Moreover, these results illustrate that consistent liming of agricultural soils, particularly near industrialized regions with high cumulative inputs of heavy metals and acid deposition, becomes increasingly important in order to stabilize the soil pH and avoid sharp and sudden increases in crop uptake of trace metals.

Since agricultural lands in the basin are well managed, and probably frequently limed, excessive cadmium intake through diet may not be a pervasive problem. Perhaps of more consequence is the possibility of changing land use. Much of the agricultural land in the basin is situated in upland areas mixed with a high percentage of forests. Because this is not considered prime agricultural land, it may one day be abandoned and converted to forest. A historical example in England (Figure 9) shows that one outcome of converting farmland to forest may be a rather fast and significant decline in soil pH in the plow layer (top 20 cm that contain the roots of crops), particularly if liming were to cease altogether. This occurrence could trigger the mobilization of sizable amounts of cadmium out of the topsoil. Some would be taken up in new vegetation, which could harm wildlife grazing on the new growth. Alternatively, there may be increased leaching of cadmium to groundwater, which could pose a threat for drinking water supplies.

Table 5 Estimated time required for a 40% reduction in cadmium from agricultural soils of the Rhine Basin[a]

Soil pH	Yearly leaching rate (percent)	Years required for 40% reduction
6.0	0.14	365
5.5	0.3	170
5.0	0.6	85
4.5	1.4	36
4.0	2.9	17

[a] Assumes organic matter content of soil to be 3.5%, and that over the time periods indicated, there are no further net inputs of cadmium to the soil.
Source: adapted from Stigliani *et al.* (1993).

In any case, this analysis begs the question: How should the toxic load of stored cadmium be managed in the face of future land use changes? The impact will depend to a great extent on the rate at which the pollutant leaches from the soil, and this rate will depend on the rate at which the pH changes. Table 5 lists the estimated times required for 40% of the soil s cadmium to leach out of the top 40 cm as a function of pH. This corresponds to an average of about 300 g of leached cadmium per hectare. For an agricultural area of 10 million hectares, total leaching would amount to about 3000 tons of cadmium. If the leaching occurred in 17 years (pH = 4.0), then the annual inputs to lower soil horizons and groundwater would be around 176 tons year^{-1}.

In some areas, allowing the lands to acidify and the metals to leach out of the topsoils as quickly as possible may be a viable option. For a topsoil with a cadmium concentration of 720 g ha^{-1} to a depth of 20 cm, the dissolved phase concentration is estimated to increase from 0.0005 to 0.006 mg l^{-1} as the soil pH declines from 6 to 4.5. Given that the primary drinking water standard for

cadmium is $0.01\,mg\,l^{-1}$ and that mobilized cadmium will be further diluted as it moves into the saturated zone, a large-scale deterioration of groundwater quality due to an increase in cadmium concentration may not be expected. On the other hand, it should be noted that significant regional variations in soil cadmium concentrations exist within the basin, and there are undoubtedly hot spots of cadmium accumulations, particularly near intensive industrial areas where inputs from atmospheric deposition and other possible sources were excessive in former times. In these areas the heavily polluted soils that overlie shallow groundwater could contaminate the water. A safer option would be to slow down the rate of leaching by controlling the rate of pH decline. For example, if the pH of the soil were lowered to 4.5 or 5.0 rather than 4.0, the rate of leaching could be reduced by one-half to one-fifth, respectively. This option would provide more assurance that vulnerable areas of the Rhine Basin would not be subjected to unduly high releases of cadmium.

REDOX POTENTIAL AS A CAPACITY-CONTROLLING PROPERTY IN SEDIMENTS AND AQUATIC ECOSYSTEMS

Organisms oxidize organic carbon (CH_2O) to obtain energy for their metabolic needs. Oxidation of CH_2O requires a reactant called an oxidant. Only six such reactants control the oxidizing power of the biosphere. These are, in order of decreasing microbial preference: (1) oxygen (O_2); (2) nitrate (NO_3^-); (3) manganese dioxide (MnO_2); (4) ferric hydroxide ($Fe(OH)_3$); (5) sulfate (SO_4^{-2}); and (6) carbon dioxide (CO_2) (*see* Redox Potential, Volume 2).

As shown in Table 6, oxidants participating in redox reactions generate chemical by-products that affect the environment in different ways. With respect to nitrate, about 5% of the time NO_3^- goes to nitrous oxide (N_2O) rather than the fully reduced product N_2. N_2O is a strong greenhouse gas (200 times more potent than CO_2 on a per molecule basis). It also is the precursor for formation of nitric oxide (NO) in the stratosphere, which plays a key role in the nitrogen chain reactions that regulate, along with chlorine, the formation and destruction of stratospheric ozone.

The oxidized forms of manganese (MnO_2) and iron ($Fe(OH_3)$) are insoluble. They are common environmental minerals that coat the surfaces of soil and sediment particles. They play a useful role in the environment because they efficiently adsorb deleterious pollutants such as PO_4^{-3}, pesticides, and heavy metals. This situation changes, however, under anaerobic conditions and in the absence of nitrate. Microbial reactions using MnO_2 and $Fe(OH)_3$ as oxidants generate the reduced products Mn^{+2} and Fe^{+2}. These are soluble forms and all the pollutants that were adsorbed to the oxidized minerals are released to the water; i.e.,

$$\{MnO_2/Fe(OH)_3\} \Leftarrow \text{(adsorbed pollutants)} \longrightarrow$$
$$\text{[insoluble oxidized state]}$$
$$\{Mn^{2+}/Fe^{2+}\} \Rightarrow \text{(soluble pollutants)}$$
$$\text{[soluble reduced state]}$$

Anaerobic microbes using sulfate (SO_4^{-2}) as an oxidant generate the sulfide ion (S^{-2}) as the reduced product. On the negative side, sulfide reacts with H^+ to form hydrogen sulfide (H_2S) gas, a deadly toxin. Sulfate-reducing bacteria (SRB) are also major players in the generation of methylmercury (Benoit *et al.*, 2001; Benoit *et al.*, 1999), a toxic substance posing high risks to human populations ingesting contaminated fish. On the positive side, other heavy metal ions form insoluble metal sulfides that render them unavailable to biota. Because of the natural abundance of sulfate in seawater, these reactions are particularly relevant in marine ecosystems, and in wetlands and soils that were once under the sea.

Methogenic bacteria are found under anaerobic conditions at extremely low redox potentials, as may be found in wetlands, flooded areas, rice paddies, and the sediments of enclosed lakes. In these conditions, bacteria produce methane (CH_4) as well as CO_2 by the disproportionation of organic carbon. CH_4 is a strong greenhouse gas

Table 6 Environmental consequences of microbial redox reactions

Oxidant	Significant reaction products	Impact
O_2	CO_2	Depends on source of organic carbon[a]
NO_3^-	N_2O	A potent greenhouse gas; player in stratospheric ozone depletion
$MnO_2/Fe(OH)_3$	Mn^{+2}/Fe^{+2}	Mobilizes PO_4^{-3}, pesticides, heavy metals
SO_4^{2-}	H_2S; methylmercury; bound metal sulfides;	H_2S and methylmercury are highly toxic; metal-bound sulfides are immobilized
CO_2	CH_4	A potent greenhouse gas

[a] CO_2 is a greenhouse gas, but will not add to the greenhouse effect if the source of organic carbon from which it is generated is renewable biomass, which is usually the case.

whose potency is about 20 times higher than CO_2 on a per molecule basis.

Sudden changes in redox potential are possible, which can lead to deleterious environmental effects that appear as surprising or unpredicted occurrences. Some examples of this behavior are described in the following discussion.

Anoxia in Coastal Waters

Anoxia may occur in intermediate or deep waters of a gulf or a fjord with restricted circulation with surface waters. Figure 10 illustrates the underlying mechanism. As carbon is gradually added to the deeper waters, O_2 is progressively consumed by aerobic bacterial activity, and since there is little mixing with the surface layers, replenishment of O_2 from the atmosphere does not occur. (Oxygen in seawater is sufficient to oxidize only about 3.4 mg of carbon per liter.) Because seawater is rich in sulfate salts, the favored reaction under anaerobic conditions is sulfate reduction to hydrogen sulfide. Although H_2S is generally confined to the lower layers of seawater, during a storm event rapid mixing of the deeper, anoxic layers with the surface layer may subject marine life to high exposures of H_2S.

In coastal areas of Denmark in 1981 (Figure 11) and again in 1983, there were unprecedented depletions of oxygen and releases of hydrogen sulfide, causing the massive killing of fish. In a comprehensive investigation, the Danish National Agency for Environmental Protection concluded that meteorological conditions had triggered the two episodes, but that the underlying cause was the increasing over-fertilization of the coastal waters with an accompanying over-abundance of oxidizable organic carbon. The source of nutrient inputs was primarily runoff of nitrogen fertilizer from cropland (Schroder, 1985). The same phenomenon was observed in the 1980s in the Gulf of Saronik near Athens, Greece. The cause in this case was not nutrient runoff from cropland, but the direct disposal of raw sewage containing large concentrations of organic carbon.

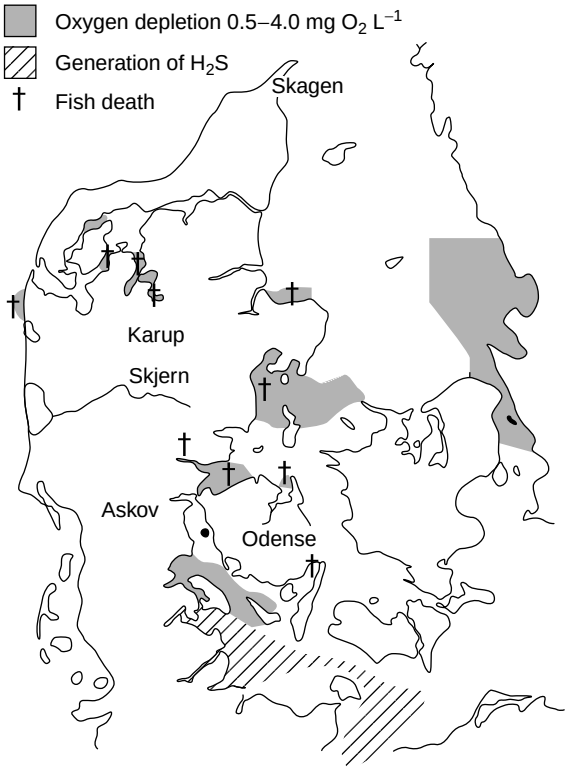

Figure 11 Scandinavian coastal areas where oxygen depletion, fish suffocation, and generation of H_2S were recorded in September 1981. (Reproduced from Miljostyrelsen, 1984)

Wetlands as Chemical Sinks

The episode of fish kills depicted in Figure 11 might have been avoided if the original coastal wetlands had not been drained. Wetlands are typically anoxic with large amounts of organic carbon; they create natural buffer zones for nearby fresh or marine waters by trapping inflowing nitrate (Figure 12a). Nitrate enters wetlands in agricultural runoff, and bacteria use it to oxidize stored carbon via the reduction of nitrate to N_2, which is vented to the atmosphere. By depleting nitrate before it enters the estuary, wetlands limit the excessive growth of biomass and subsequent anoxic conditions in the estuary waters. Furthermore, if wetlands are of marine origin, they are likely to contain high concentrations of sulfur in the form of reduced sulfide minerals such as pyrite. Under the redox/pH conditions prevalent in wetlands, these sulfides are highly insoluble and immobilized.

Draining wetlands radically changes the chemistry of the landscape (compare Figure 12a to Figure 12b). Nitrates enter receiving waters unmitigated, and sulfides, upon exposure to the atmosphere, are oxidized to sulfates. In contrast to sulfides, sulfate salts are appreciably soluble. Thus, draining wetlands can trigger the release of mobilized H_2SO_4, or heavy metal sulfates (e.g., $CdSO_4$, or $ZnSO_4$).

An example of this phenomenon occurred in a coastal area of Sweden near the Gulf of Bothnia, where wetlands were first drained in the early 1900s and more extensively in the 1940s for conversion to agricultural lands. The draining exposed sulfides to atmospheric O_2, resulting in their oxidation to H_2SO_4. Runoff from the drained land during storm events acidified nearby lakes. The pH in one of these lakes, Lake Blamissusjon, dropped from about 5.5 in the 19th century to a current value of around 3. Even though agricultural activities ceased in the 1960s, the lake has not recovered; it is widely known as the most acidic lake in Sweden. Similar problems occur on the global scale (*see* Acid Sulfate Soils, Volume 3).

Methylation of Heavy Metals

Bacterial methylation of metals such as mercury (Hg), arsenic (As), and tin (Sn) is a major concern because of the toxicities of the generated organo-metallic products. Most worrisome have been risks to the environment and human health posed by the methylmercury ion (CH_3Hg^+). Inorganic mercury, in any of its common valence states Hg^0, $Hg_2{}^{+2}$, and Hg^{+2}, is not particularly toxic when ingested; it tends to pass through the digestive system, although Hg^0 is highly toxic when inhaled. But CH_3Hg^+ is extremely toxic, regardless of its route of exposure.

Two CCPs, redox potential and microbial activity (see Table 1), play a crucial role in the generation of CH_3Hg^+ in the environment. The key microbes appear to be the same sulfate reducing bacteria (SRB) that thrive under low redox conditions in the presence of sulfate (Benoit *et al.*, 2001; Benoit *et al.*, 1999). In sediments contaminated with sulfur and mercury, SRBs transform mercury into the complex HgS^0. Because it is a neutral molecule (i.e., without charge), it is lipophilic and readily crosses bacterial cell membranes. Once inside the cell, SRBs synthesize methylmercury via the action of methylcobalamin, a derivative of vitamin B_{12} with a $CH_3{}^-$ anion bound to cobalt. The bacteria then eject the methylated product into the water, where it is absorbed by fish from water passed across their gills or from their food supply. CH_3Hg^+ forms CH_3HgCl in the saline milieu of a fish s biological fluids. This neutral complex crosses biological membranes, distributing itself throughout the fish tissue, in which the chloride is displaced by protein and peptide sulfhydryl groups. Because of mercury s high affinity for

sulfur ligands, CH_3Hg^+ is eliminated only slowly and is therefore subject to bioaccumulation when little fish are eaten by bigger fish. The phenomenon is the same as for DDT and other lipophiles, but the mechanism is different because mercury accumulates in protein-laden tissue (the edible part of the fish) rather than in fat.

Humans ingesting large quantities of fish contaminated with methylmercury suffer serious health effects. These include numbness in the limbs, blurring and even loss of vision, and loss of hearing and muscle coordination all symptoms of brain dysfunction resulting from the ability of methylmercury to cross the blood brain barrier. Likewise methylmercury can pass from mother to fetus, resulting in mental retardation and motor disturbance in newborns.

Minamata: an Exploded CTB

The Minamata catastrophe of the 1950s alerted the world to the gravity of mercury toxification (Harada, 1995). A polyvinylchloride factory near the fishing village of Minamata, Japan used Hg^{+2} as a catalyst, and discharged mercury-laden residues directly into the fishing waters of Minamata Bay. At the time, conventional wisdom viewed mercury in sediments as biologically inert. Given its high density (13.6 times the density of water), it was thought that the metal would sink out of harm s way into the sediments. The generation of methylmercury by bacteria was unknown. In a clear example of a CTB, the chain of events from the dumped inorganic mercury waste to its accumulation in the form of methylmercury in the aquatic food chain was unexpected and not understood until the damage was already done. The fish consumed by the villagers had accumulated methylmercury to levels approaching 100 ppm. Thousands were poisoned, and hundreds died from it (*see* Fisheries: Minamata Disease, Volume 3).

The Amazon Basin: a Ticking CTB

Although it would seem that one Minamata type disaster would be enough to curtail unsafe uses and disposal of mercury, an ongoing CH_3Hg^+ poisoning episode is playing out on a much grander scale in the Basin of the Amazon River in Brazil (Lacerda *et al.*, 1995) (*see* Mercury in the Environment, Volume 2). Over the past 35 years, prospectors have used mercury as an amalgam to extract trace amounts of gold from dredged sediments in several tributaries of the Amazon River. The gold is separated from the amalgam by roasting it in pans in open air (temperatures of 350 600 °C). It is estimated that about 130 tons of mercury each year are released in the Basin from this activity. Figure 13 shows the fate of the mercury in the amalgam; about half escapes to the air and the remainder is lost directly to the rivers in the form of metallic mercury (Hg^0). In the atmosphere it is oxidized to Hg^{+2} and returned to the land by atmospheric deposition. Runoff from the land causes the input of additional mercury into the numerous tributaries that feed into the Amazon.

In recent years, another important and more spatially diffuse source of CH_3Hg^+ has been discovered (Roulet *et al.*, 1998, 1999). The forest soils of the Amazon Basin possess naturally high concentrations of mercury (19 33 mg m^{-2} in the top 20 cm). The top organic layer adsorbs mercury on constituent humic materials, and the deeper mineral layers adsorb it on clays and iron oxides (the same mineral that locks cadmium in the soils of Shipham, England, as noted in Table 4). Conversion of these lands to agriculture by the slash and burn method burns off much of the top organic layer, leaving behind a mobile, mercury-containing residue. Additionally, the newly exposed mineral layer is subject to significantly enhanced rates of erosion, during which combustion residues, fine clay constituents, and associated iron oxides, all of which contain mercury, are preferentially exported from the soil and delivered to rivers via runoff during storms. The preferential leaching of clay and iron oxides acidifies the remaining soil, which further increases the rate of mercury exportation. Roulet *et al.* (1999) estimate that erosion of the top 1 cm of soil from deforested land mobilizes 500 3000 μg Hg m^{-2}. The total estimated deforested land in the Amazon is 270 000 400 000 km^2. This implies that erosion of 1 cm from this land mobilizes 135 1200 tons of mercury. Total soil loss of mercury from the top 10 cm could be ten-fold larger, although not all of the eroded mercury will end up in the basin s aquatic ecosystems.

The mercury load to the rivers has caused elevated concentrations of CH_3Hg^+ in carnivorous fish in the Madeira and Tapajos Rivers (Lacerda *et al.*, 1995; Lebel *et al.*, 1997). Compared to background mercury concentrations in fish of 0.2 μg g^{-1} in unpolluted freshwaters and less than

$0.15\,\mu g\,g^{-1}$ in oceans, carnivorous fish in the Madeira River have an average mercury burden of $0.70\,\mu g\,g^{-1}$, with a range from 0.07 to $2.89\,\mu g\,g^{-1}$; in the Tapajos River it averages $0.55\,\mu g\,g^{-1}$, with a range from 0.04 to $3.77\,\mu g\,g^{-1}$. These numbers are for the most part greater than the $0.5\,\mu g\,g^{-1}$ limit established by Brazilian legislation in 1975.

An overall assessment of the extent of human intake of CH_3Hg^+ and the prevalence of disease symptoms among exposed populations is hampered by lack of data, particularly in the most remote Amazonian populations. Nevertheless, existing and ongoing studies provide a worrisome indication that the sequence of steps from initial input of mercury to the aquatic environment to uptake of methylmercury in the human diet is already in place, at least in some parts of the basin.

Human hair is a good indicator for assessing CH_3Hg^+ contamination in exposed populations as it reflects blood concentration at the moment hair is being formed. Detailed hair mercury studies were conducted in towns and villages near the Mediera and Tapajos Rivers; the results are shown in Table 7. These values may be compared to $6\,\mu g\,g^{-1}$, the limit set by the Brazilian government for indication of mercury stress in an individual. In the Tapajos River Basin, the elevated levels in the upstream towns may reflect their proximity to the gold mining areas, and perhaps differences in diet relative to the downstream towns. The relatively low levels found in gold miners in the Madeira River Basin is probably due to a diet less oriented toward fish.

Research groups from Japan and Canada have independently concluded that Minamata disease has spread to remote fishing villages in the Amazon rainforest. The Japanese investigators examined 50 people from 10 villages around San Luis do Tapajos, near the site of gold mining activities. They found that three among this group suffered from nervous symptoms peculiar to Minamata disease, including fits of trembling (Pearce, 1999). The Canadians studied other remote sites and found evidence for early nervous system dysfunction associated with low level methylmercury exposure (Dolbec *et al.*, 2000; Lebel *et al.*, 1998, 1996). Both teams agreed that the Amazon poisoning appears to be widespread, and that additional victims will likely be found across the basin, particularly if gold mining and deforestation continue unabated.

The story of mercury toxification in the Amazon Basin is a clear example of a CTB. Three CCPs defined in Table 1 (CEC, pH, and OM content) regulate mercury adsorption in the soils, and deforestation affects all three CCPs (see Table 2). Eh, a fourth CCP, changes when mercury mobilization and erosion processes transport the metal from land to rivers. In this new aquatic environment, the soil particles sink to the sediments where anaerobic conditions (i.e., lower redox conditions) prevail. As noted earlier, the iron oxides are reduced to form dissolved Fe^{+2} accompanied by the release of the mercury, which then undergoes microbial methylation to form CH_3Hg^+. This is bioaccumulated in fish, and subsequently taken up in the human diet.

Table 7 Mercury concentrations in hair samples ($\mu g\,g^{-1}$) of populations and gold miners living near the Madeira and Tapajos rivers

	Mean	Range	N[a]
Madeira river			
Riverine population (females)	9.2	0.6–37.2	22
Riverine population (males)	11.8	0.5–71.4	25
Gold miners (males)	5.3	0.2–24.2	30
Tapajos river			
Upstream			
Jacareacanga	25.5	5.7–51.6	10
Brasilia Legal	26.0	4.8–151.2	55
Downstream			
Ponta de Pedras	11.4	6.9–22.3	46
Cameta	9.0	5.5–12.5	68
Santarem	2.7	0.7–6.5	11

[a] Signifies number of samples.
Sources: all data from Lacerda *et al.* (1995), except for Cameta, which is taken from Dolbec *et al.* (2000).

CTBs AND CLIMATE CHANGE

As noted in Table 2, the CCPs that determine CTB behavior by heavy metals in soils and sediments are affected by climatic factors and sea level rise. The climate/CTB pyramid shown in Figure 14 indicates the complex linkages between

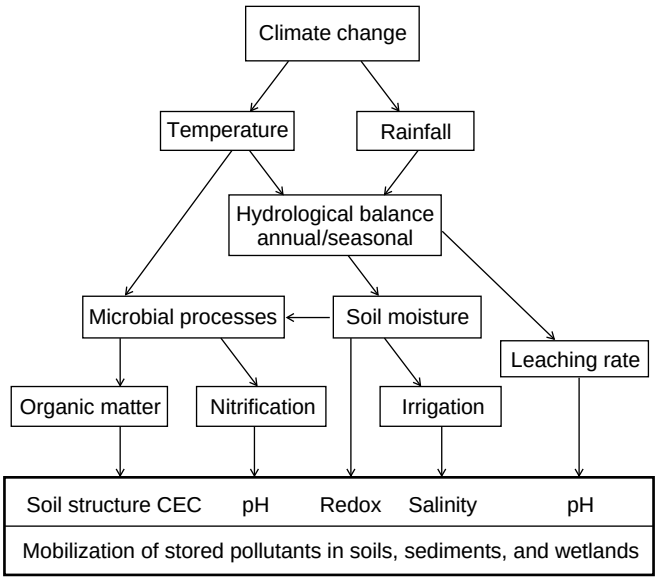

Figure 14 The climate/CTB Pyramid. (Reproduced from W M Stigliani and W Salomons (1993) Personal communication, IIASA, Laxenburg, Austria)

the two. A fundamental question is whether the chemicals stored in the biosphere under current climatic conditions will remain stored under a new climatic regime? Or will the changing climate transform current pollutant sinks into pollutant sources?

The Arctic regions of the world have served as vast sinks for volatile organochlorine chemicals, the most important of which have been PCBs, and the pesticides DDT, hexachlorocyclohexane (HCH), chlordane, and toxaphene. They concentrate in water, ice, and snow, and are taken up by fish, mammals, and humans. This has led to concern for the health impacts on native people who consume traditional foods such as seals and other aquatic species.

These organochlorine chemicals are transported to the Arctic via two mechanisms. One is normal atmospheric transport, which is a fast, episodic process. The second is the so-called *global distillation effect*, which is driven by the temperature gradient between the equator and the poles. By this process the chemicals generated in the Northern Hemisphere gradually make their way northward through evaporation, and then preferentially condense in the Arctic because of the coldness of the air and oceans. For example, it is estimated that the upper 200 meters of the Arctic Ocean contain 8.1 kilotons of HCH (Harner, 1997).

The greatest temperature increases from global warming are expected to occur at the poles. If this happens, the temperature gradient between the equator and the poles will decline, and the global distillation effect may not be as pronounced. As noted by Harner (1997) this may cause reduced polar-bound transport of pollutants, resulting in a redistribution of the organochlorines on a global scale. Moreover, if the warmer temperatures decrease the mass of ice cover, the melting ice would release pollutants long stored inside the mass.

On the other hand, polar warming may have the opposite effect (Harner, 1997). It could increase Arctic water evaporation and precipitation as snowfall, resulting in an accumulation of ice pack, and increased storage of the pollutants. Additionally, global warming is likely to increase ocean temperatures. This could lead to increased volatilization of the organochlorines in the tropical and temperate oceans, and enhanced transport to the colder regions (Iwata *et al.*, 1993). In any case, climate change is likely to redistribute the sources and sinks for these pollutants worldwide, in ways that are currently too uncertain to identify and quantify.

CONCLUSION

In recent decades, industrial societies have become acutely aware of the problems caused by the inappropriate disposal of toxic industrial wastes, the legacy of earlier generations that favored expediency over precaution. Typically these wastes were contained in metal drums and buried haphazardly in dumpsites near large industrial centers. The problem of course is that metal drums corrode over time and eventually leak, causing the stored chemicals to disperse to the wider environment. In actuality the storage, accumulation and eventual release of deleterious chemicals in the environment is far more pervasive than the single issue of toxic waste dumpsites and their management. In a broader sense, the mobilization and spread of chemicals in the biosphere now has global implications. No place on earth has been spared. In the Arctic, PCBs show up in the adipose tissue of polar bears. In the South Pacific, radioactive fallout threatens inhabitants of the Solomon Islands and Guam, while some islands of the Marshalls have been rendered permanently uninhabitable. In the remotest parts of the Amazon rainforest, mercury is poisoning indigenous populations.

The world over, activities that pollute the environment have been condoned and even encouraged in part because they provide instant service or profit without apparent adverse effects. This dynamic seems to work because the biosphere can store and accumulate toxic wastes out of harm s way for a long time. At first glance, this creates the impression of an environment that is infinitely forgiving of our wanton disregard for maintaining pollution within the limits imposed by natural buffering capacities.

But as discussed in this paper, these capacities are exhaustible either through direct saturation, or changing environmental conditions that shrink the ability in soils and sediments to store and retain harmful chemicals. Once pollutant inputs exceed natural limits for their safe assimilation we set in motion a retoxification process that is usually unpredictable and unexpected. Chemicals long stored are released and mobilized, analogous to the way toxic chemicals leak from corroded containers in a toxic waste dump. Leaks in the biosphere, however, are of more concern. Replenishment of depleted buffering capacities takes a long time, and in some cases the damage is irreversible. Moreover, the spatial scale of damage can be far more extensive than that of an industrial toxic waste site. Buffering capacities are valuable and often unappreciated natural resources. Maintaining them should be an important component in the evolution of an economy based on ecological sustainability of the biosphere.

Rice and its Spread: Double Cropping; New Varieties – Environmental Consequences and Methane Gas, Sustainability

R D HILL

The University of Hong Kong, Hong Kong

*Rice the world s most popular food for man and beast! Rice the word for food in a dozen Asian languages! Amongst the grasses (*Graminae*) rice is pre-eminent. Roughly three billion people and countless animals eat it as a major source of carbohydrate. It also contains fats and proteins, especially in its unpolished, thus more nutritive form. Of the two species of cultivated rice, that of Asian origin,* Oryza sativa*, L., is by far the most widespread. The indigenous West African species* O. glaberrima *has spread little from its homeland and in the continent as a whole,* O. sativa *is now at least as common as its African cousin. (The North American wild rice,* Zinzania aquatica*, is a very distant relative of the cultivated species though belonging to the same botanical tribe, the Oryzeae). Over the last four decades rice has steadily expanded its share of the global grain production area to 21% and to 27% of total grain produced from 18% and 26%, respectively, in the early 1960s.*

Physiologically, rices are swamp-dwelling plants and one of the major consequences of their domestication has been the requirement both to adapt many different kinds of tropical and temperate environments to their needs and to select varieties for a range of conditions. The yields of cultivated rice are highly responsive to increased labor inputs aimed at optimally matching the characteristics of each of the many thousands of varieties of O. sativa *especially to local micro-environments. Thus transplanting, which reduces competition with weeds, close planting, frequent weeding, tight control over water-supply and general good husbandry, each implying higher levels of environmental modification and control, are needed to obtain maximum returns. The result may be an almost total remaking of the habitat, especially in wet-terrace cultivation. The other major response has been to adapt the rice plants physiology to other environments, slightly saline ones along coasts or drier ones on hill slopes, a process probably occurring later than initial domestication though still prehistoric. Such selection has continued, of course, especially since the 1950s when the problem of feeding Asia s rapidly expanding population became pressing. In order to maximize yields, the basic scientific strategy has been to breed high-yielding varieties (HYV s) that require a high level of inputs and precise ordering of the conditions in which they are grown.*

From a homeland in East and Southeast Asia, O. sativa *spread widely, beginning perhaps eight thousand years ago. It reached the Middle East and possibly coastal East Africa two millennia ago, Southern Europe patchily from the fourteenth to the nineteenth century and was well established in the Americas by the eighteenth century.*

Systems of rice production are quite varied, though probably less so now than before the wide adoption of HYVs. Rice is grown commercially in subtropical areas of the United States, Australia and Southern Europe as an element in rotational cropping. It is grown as a mono-crop for the subsistence of millions of Asian families. The strength of this direct support for life is re ected in the fact that only about 4% of rice produced enters international trade. Most is consumed directly as human food but some feeds animals: in Australia sheep lightly graze the growing plants, adding dung to the soil. Rice polishings and poor-quality grain are widely used to feed pigs and poultry. Some is used industrially, about 40% of the US crop for beer, while in Asia rice wine is commonly made both domestically and commercially. A major by-product, rice husk, is highly siliceous and is of little use except as fuel and for cleaning the interior of jet engines.

The total amount of land modi ed for and by the cultivation of rice is not known. Data from the Food and Agricultural Organization of the United Nations (FAO) indicate a current harvested area of about 150 million hectares but this includes an element of double counting since signi cant areas are cropped with rice twice annually, with some, mainly in Java, being used even more intensively. International Rice Research Institute (IRRI) data indicate that about 24% of the rice area is double-cropped with rice while a further unknown fraction also grows rice and another crop. The area currently growing rice under shifting cultivation is not known either but given that the customary bush-fallow is seven to ten years after a year or two of cropping, the area now affected by clearance for this dry form of cultivation must be three to ten times greater than the area actually growing rice at any time. The degree of environmental impact by rice cultivation varies with the intensity of land use, ranging from an almost total remaking of the environment in wet-terrace cultivation such as in Java, North-central Luzon and many parts of Southern and Southwestern China to relatively little change in long-fallow systems of shifting cultivation such as survive in remote areas of Indochina. Lowland systems, where soils are wet and high in organic matter, are a major global source of methane (CH_4), an important greenhouse gas.

ORIGINS

The genus *Oryza* comprises 20 or so species of aquatic grasses that are native to permanently or seasonally flooded sites in tropical and subtropical regions around the world so long as these are not particularly saline or acid. In detail their distributions show remarkable disjunction, the reasons for which are unclear. Notable is the disjunction between the two cultivated species, *O. glaberrima*, whose home is in West Africa and *O. sativa* whose home is a matter of debate but almost certainly in one or more parts of a large region extending from the lower Yangtze valley in central China, through South China, mainland Southeast Asia and the margins of the Bay of Bengal as far west as the Indian state of Orissa. In this zone grow a number of possible wild ancestors, of which the closest relatives of *O. sativa* are *O. nivara*, a wild annual, and *O. perennis*, a perennial. The latter is thought to have contributed genetically to floating varieties of *O. sativa* that have the capacity to elongate their internodes in response to rapid rises in water level.

The environment in which rice was domesticated can be established with some certainty, for all rices are tropical and subtropical swamp grasses. But where were such swamps, given that some authorities argue that such regions naturally have a forest climate? Grassy swamps can have been of very restricted distribution, perhaps occupying lake margins and flood plains where trees could become established only with difficulty by reason of fluctuating water levels and the deposition of flood debris. But Paleolithic peoples almost certainly possessed fire and unquestionably used it directly to assist in hunting and may also have used it, consciously or unconsciously, to modify tree vegetation, for in monsoonal climates, standing forest will burn in dry seasons. Grassy swamps, even with standing water will also burn in the same season. The effects would likely have been to increase carbohydrate sources for gathering and to increase the number of grazing animals for hunting. There is as yet insufficient palynological evidence to confirm such a scenario but in historical times it is known that very extensive grassy swamps existed for instance in the Brahmaputra-Ganges delta and along the Chao Phrya river.

What is certain is that rices cannot have been domesticated in temperate climes, whether in higher latitudes or at higher altitudes in the tropics. Nor can they have been domesticated in the equatorial zone, for traditional varieties of *O. sativa* are highly photosensitive, requiring long days to initiate flowering and the formation of the grain. In the Peninsular Malaysian state of Negeri Sembilan, for instance, experiments in the nineteenth century showed that rice planted out of season simply remained at the initial vegetative stage of growth, flowering only when days lengthened. (The varieties used had probably already been selected for sensitivity to small differences in day-length, at that location barely half an hour). Equally, neither domesticated rice nor agricultural systems based upon it could have arisen on hill-slopes for rice is physiologically a swamp plant so that drought-tolerance is necessarily not a feature of original domesticates. Much the same considerations apply to brackish-water tolerance, a capability clearly bred into rice by selection. However, with some exception in respect of cold-tolerance, just when these characteristics were acquired is simply not known, in part because these questions have been little studied. The Japanese case is instructive. Arriving in the south about 2300 years ago, rice moved slowly north, not reaching Northern Honshu until the seventeenth century and Hokkaido two centuries later, a process clearly dependent upon the development of successively more cold-tolerant varieties and of methods to warm irrigation water using the sun s heat.

The key to domestication was the selection of rice that did not shatter, shedding the grain when ripe. That selection did not necessarily occur by the time that rice came to be cultivated. Oka and Chang (1959) argued, on the basis of experimental study of the effects of human impact upon wild rices, that, ••• the degree to which

genotypes of a population [of wild rices] approaches that of the cultivated form is related to the degree of disturbance by man ••• Should this be so, then within the range of wild progenitors, domestication need not have been a once-for-all occurrence.

However, most prehistorians argue that such once-for-all domestication is the norm rather than the exception. But what is meant by domestication? Loss of shattering is one of the characteristics but this can scarcely be expected to show up in the archeological record. Loss of awns (long hairs on the grain), on the other hand does show up in the record. Several stages of domestication may be envisaged. First, desired rice plants would have been protected but no more than this. Second, grain would have been deliberately sown but with little or no clearing of the vegetation to receive it. This practice survived into the nineteenth century in the Malay Peninsula, as *padi terbuang* literally thrown rice. Yields would have been low because of competition with other plants so that clearance by fire and/or weeding unquestionably would have increased them. This may well have been a third stage. A further step in enhancing yields by reducing competition with weeds would have been tillage, probably at first using the hoe, an implement still used in preference to the animal-drawn plough in many parts of Asia into the 1960s. Other yield-enhancing technological advances include transplanting, fertilizer application and close control of water by irrigation, advances which have been made at very various times and places down to the present time. At some point, probably quite early, *Oryza sativa* came to be treated as an annual, for even today rice stubble will produce a second or *ratoon crop* if permitted to do so though yields are much less than the first time around. A comment in the Chinese *History of the Chin Dynasty (AD 265- 419)*, referring to the Mekong kingdom of Funan, suggests just such a practice. The general picture is thus one of increasingly intensive production, doubtless with regressions and diversions on the way, each involving increased environmental control and biological simplification as rice, once one crop amongst many, has become a highly labor-intensive monoculture.

SPREAD

What do prehistory and the archaeological record have to say about the broad picture presented here? Because of the wide distribution of wild and weedy races of *Oryza* in east and Southeast Asia and because of extensive hybridization, an accurate delimitation of a place of origin of the domesticated plant on the basis of living plants is not feasible. This is so not least because wild rices are common weeds in rice-fields. Thus in Peninsular Malaysia are found *Oryza fatua* and *O. minuta*, both bird rice to indigenes, both, like *O. sativa*, light-lovers, both crossbreeding with each other and with cultivated rice. (A third wild rice, *O. ridleyi*, is a shade-loving dweller of forest margins that has probably played no part in the game).

Theories are complicated for both pragmatic and political reasons. India, mainland Southeast Asia and China have all been touted as earliest homes of domesticated rice in Asia, following a once-for-all interpretation. A serious technical difficulty is that various characteristics of grain shape and size are not necessarily clearly diagnostic of domestication, a conclusion reached by Douglas Yen concerning imprints on pottery found at Ban Chiang, Thailand, dated about 2000 BC and by TT Chang with respect to Philippines material of 1240 BC. Another problem is that the extraction of plant remains from excavated debris at archeological sites, and analysis by C^{14} dating, has not necessarily been carried out, so that claims of great antiquity may not be firmly established. If Chinese claims are accepted, rice was cultivated in the Huai valley c. 8000 9000 years ago and a thousand years later in the Yangtze valley. These areas are on the margin of the generally accepted zone of Asian wild rices rather than at its core as postulated by the noted Russian botanist Vavilov. This apparently was the beginning of at least some of the processes of rice-induced environmental change that still continue. Rice impressions of Neolithic age have been found near Allahabad, India, dating 6000 7000 thousand years ago and from Thailand some 5000 years ago but it is not clear that these are truly cultivated varieties. In Southern China the earliest sites with the rice remains date from 4000 to 5000 years ago but that relatively moist region, like Southeast Asia, is not one that is conducive to the preservation of remains, unless carbonized, and it is possible that future work will turn up evidence of earlier use (Figure 1).

So far as progressive intensification of production and environmental impact is concerned, the evidence of archeology is complex and confused. What are interpreted as stone hoe blades appear early in the record but are not necessarily associated with preserved evidence of rice. Ploughs are certainly later but, like rice itself, appear to have spread at extremely uneven rates, having been introduced or possibly reintroduced, in Sarawak as recently as the nineteenth century. Irrigation works are notoriously difficult to date though Sri Lanka s are claimed to be at least 1000 years old. In the deltaic regions, irrigation works were probably long preceded by drainage works as for example those at Oc-Eo on the lower Mekong dating from the fifth century AD. In such areas the means of raising water from drains to fields may be quite late, the Chinese pedal-powered pump, probably little more than 1500 years old in its homeland, having been used for no more than 200 years in the lower Mekong at best.

Once into historical times, we are on firmer ground in attempting to document the spread of rice, though not necessarily the spread of related engineering and water management strategies. The crop s spread to the northeast

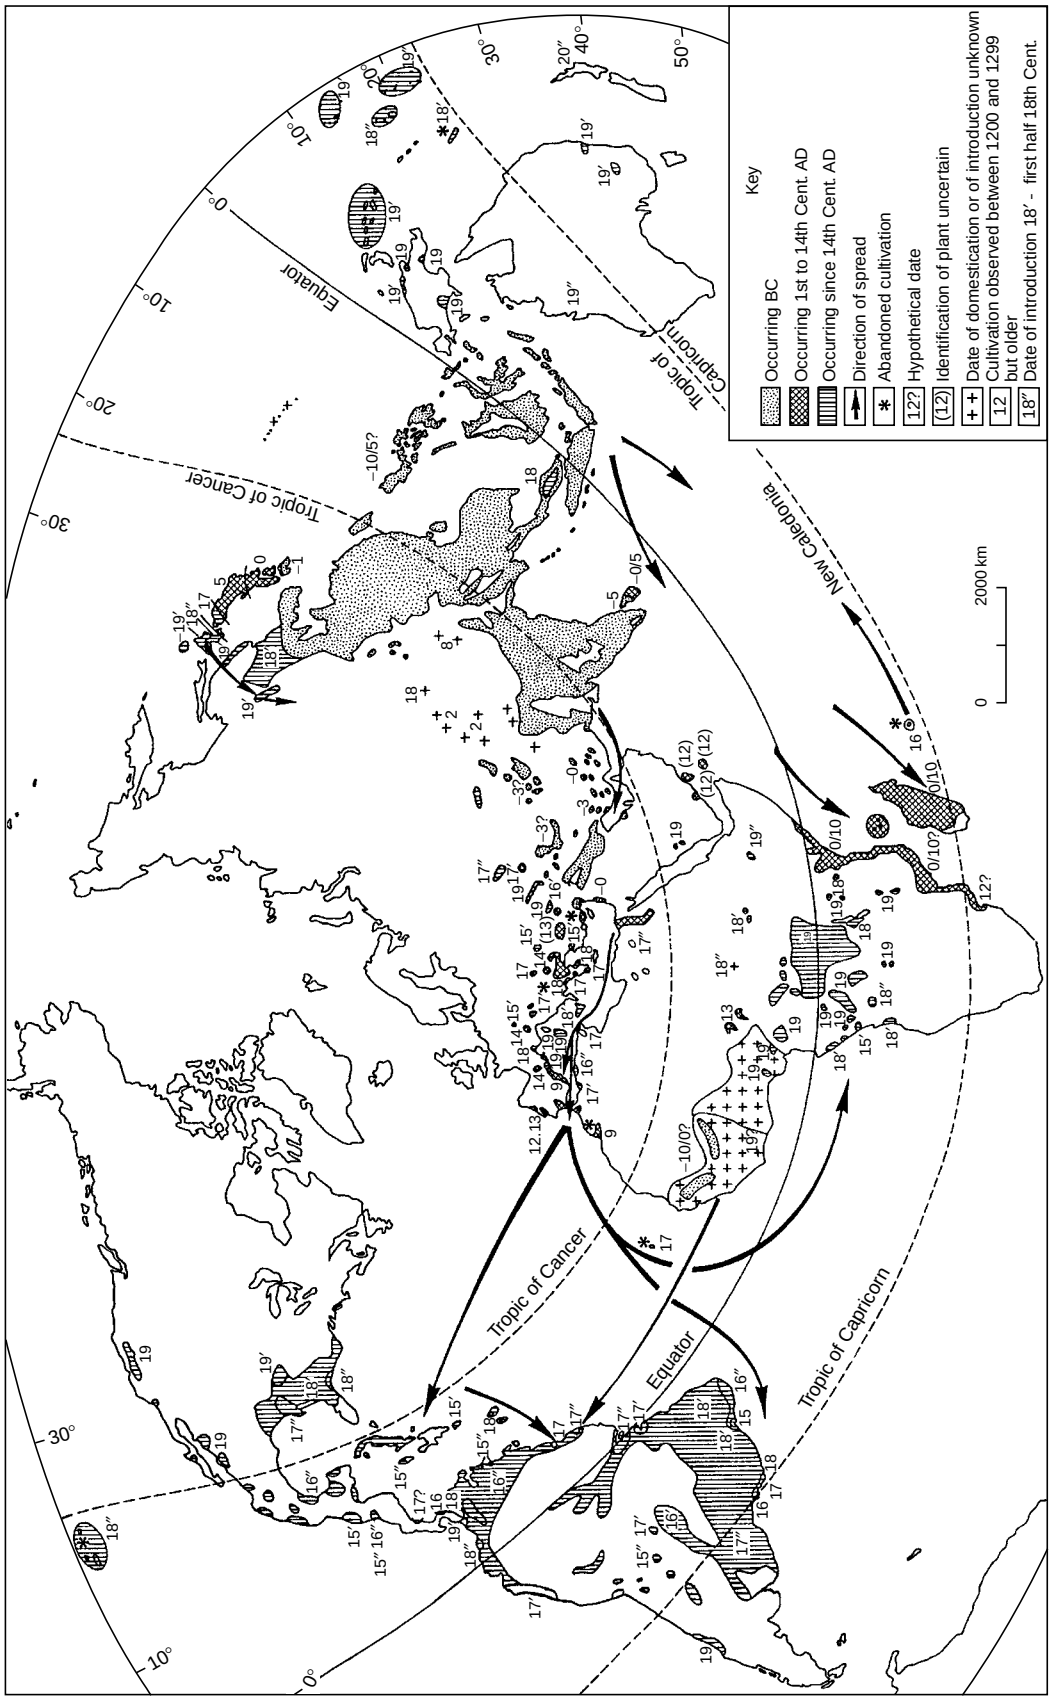

Figure 1 The global spread of rice (inventaire geographique et chronologique pour un atlas d'histoire mondiale (Paris, 1968) updated by R Hill)

has been mentioned already with its arrival in Japan about 300 BC. Its emergence in insular Southeast Asia, in Java, probably dates back to no more than 2000 BC, at the very earliest but its penetration is clearly very uneven. It did not reach Nias and Enggano, islands off Western Sumatra, until colonial times. In upland central peninsular Malaysia, aboriginal peoples have a story of a millet king, who, after a great battle was displaced by a rice king, whilst to the south of the Peninsula, late nineteenth-century aboriginals were growing the American tuber *manioc* rather than rice, the latter not being reported until the 1960s.

No one really knows why rice did not spread from Southeast Asia into the Paci c along with the Austronesian ancestors of present-day Polynesian, Micronesian and other Paci c Island peoples. The migrating Austronesians may not have had it or did but discontinued its cultivation. The latter is more likely for early in the rst millennium AD people from what is now Indonesia crossed the Indian Ocean to colonize Madagascar. Their descendants are the Malagasy people and rice elds are a major feature of the island s cultural landscape. Farther north, rice reached Western India quite early but encountered the barrier of dryness, no longer being capable of being grown in rain-fed conditions. By about the second century BC, both Chinese and Greek sources reported rice cultivation in Persia and Mesopotamia (now mainly Iraq). The spread of rice into Europe was by no means an even east west progression, certainly being in Moorish Spain by the 10th century AD. Its Arabic name *eruz* has entered many European languages, for instance as *arroz*. The earliest cultivation in Italy s Pontine marshes dates only from the 15th century where it was long hindered by the existence of endemic malaria. The growing of rice under unirrigated conditions and/or as part of a crop rotation in Europe seems to have begun in the eighteenth century.

It was from Europe that *O. sativa* spread to tropical and subtropical parts of the Americas, beginning in the sixteenth century. A further route of dispersal was from Europe to parts of central Africa and by the nineteenth century it was also being grown in the West African homeland of *O. glaberrima*. That species, however, has seemingly not spread beyond its zone of domestication though little is known of it generally. The growing of rice in Australia, New Zealand and the Paci c islands is mostly little more than a century old, the Australasian system being particularly interesting because it involves rotational farming and grazing by sheep. (Australia is a signi cant rice exporter).

The discussion thus far has concentrated upon the spread of rice to regions previously lacking it. But even in regions that have possessed rice for millennia, the area under rice has expanded enormously, especially over the last two centuries, partly in response to population growth, partly in response to growth in international trade and the international division of labor. In Asia, for example, the rice-eating population has more than doubled over the last 40 years. While there is good evidence of a per person reduction in rice-consumption in wealthy Asian regions, notably Japan, Singapore and Hong Kong, the general trend has been an expansion of demand and production, at rst largely met by expansion of the cultivated area without much increase in yield. This seems to have been at about 1.0 1.5 tonnes per hectare ($t\,ha^{\bullet\,1}$) for centuries, perhaps millennia.

Much of the expansion in countries that were already rice consuming took place in Southeast Asia as the imperialist powers insisted upon opening markets. Thus Lower Burma, centered on Rangoon (Yangon) and the Chao Phrya plain, centered on Bangkok, saw large and rapid expansions beginning from the mid-nineteenth century. This was followed by similar growth in the Mekong delta as French and Sino-Vietnamese capital owed in at the very end of the nineteenth century and early in the twentieth. In the Chao Phrya and Mekong, the initial stage was canal cutting to ensure adequate drainage, followed by massive deforestation. At rst, cultivation intensity and yields of grain were low but within 5 10 years, the remaining debris rotted away, and tillage and transplanting replaced broadcast sowing. Yields rose for a period and then fell to a stable level around $1\,t\,ha^{\bullet\,1}$ or a little more. These clearances must have involved a major addition to atmospheric carbon dioxide (CO_2) though no estimates have been made and increases would have been masked by simultaneous increases in European and American industrial CO_2 emissions. Ironically, much of the rice produced went to feed workers in just those CO_2 producing industries though some also owed to feed plantation workers in the region, themselves by the late nineteenth century responsible for major forest clearances for perennial crops such as coffee, tea, coconut, and later, rubber and oil palm.

Clearances for rice have decreased markedly since about 1950 though data do not exist. (The standard statistical series are for area harvested and for production.) At the same time cultivation intensity has increased substantially in Southeast Asia especially, though two crops a year have been usual in most of the main production areas of the Indian subcontinent, China, Northern Vietnam, Java and Bali or possibly three for four centuries, sometimes longer. The consequence is that it is impossible to say how much new land is being developed for rice, as it unquestionably is in parts of West Africa especially, or how much is going out of production as some is. In the Southern Chinese province of Guangdong for example, factories now occupy highly productive rice lands. Other areas are planted to less labor demanding crops or simply abandoned as farmers leave the land for better-paying urban

jobs Guangdong again, Malaysia and parts of Java are examples.

From the standpoint of environmental effects, the period of large CO_2 additions from land clearance for rice are long past. But CH_4 emissions continue to expand as crop intensities increase. Since the mid-1950s the harvested area, production and grain yield have risen substantially (Table 1) though with the widespread adoption of dwarf HYVs, it is possible that actual phytomass production per unit of area has fallen somewhat.

Since 1950 the global harvested area has increased by 43% but by only 8% in the 24 years to 2000 (Table 2). While the distribution amongst the main rice-growing regions has remained much the same, the once less-important regions Africa, South America, Rest of Asia and Oceania (mainly Australia) have increased their shares substantially, more than doubling their rice areas in four decades. In these the cultivation intensity is low usually a single crop annually, whereas elsewhere, except in North America, at least two-fifths of the rice land grows two crops a year. (A further but unknown proportion grows a summer rice crop and some other crop in winter).

Table 2 Average yields (t ha^{-1}) by major region, mid-1950s, 1976, 1996

Region	1950s	1976	2000

Yields are another matter. These reflect genetic characteristics, cultivation practices, water supply and control as well as sunlight. It is notable that yields are especially high in sunny regions, even if not tropical, other things being equal. Temperate production areas have longer daylight hours in summer. Some are rich and can afford to make free use of artificial fertilizers, especially nitrogenous ones, herbicides and insecticides. Only in China are comparable yields obtained, there by the heavy use of organic fertilizers, with significant consequences for CH_4 emissions. Globally, yields have doubled in four decades, the most rapid increase being between 1976 and 1986. Below average rates of yield increase occurred in Africa, where yields are low and also in the Rest of Asia where they are moderate. It is unlikely that yields will increase much beyond the 5.5 6.5 t ha^{-1} already achieved in temperate regions and in East Asia, for there is clear evidence of diminishing returns to increased and improved inputs. The United States, however, should be able to achieve Australia s remarkable 9.7 t ha^{-1}.

Overall, in most parts of Asia the spread of rice has slowed dramatically within the last two decades, in its older production areas a century or more ago. One reason is the high cost of development roughly US$20 000 ha^{-1} at which it is scarcely possible to break given current prices. Where the opportunity cost of labor is low, as in much of Africa south of the Sahara and where significant areas of alluvial lowland remain available for development, such as the Niger delta and in Sierra Leone, pioneer clearance for rice may continue. In Southeast Asia, where the opportunity cost of labor may be diminishing somewhat, the concern is that remaining upland, mainly secondary forest areas, may be attacked for rice-based shifting cultivation or that scrub fallows in existing areas where this system is practiced will be further reduced. This would almost certainly lead to enhanced upland erosion and sedimentation in the lowlands.

RICE SELECTION, BREEDING, HIGH YIELDING VARIETIES

As noted earlier, cultivated rice is by origin a plant of seasonal or permanent swamps. Selection has aimed to match varieties with varied environmental characteristics day-length of growing season, depth of standing water (or none on hill slopes), speed of change in water depth, maturation period, drought resistance, fertilizer response, degree of shattering, color, taste, milling characteristics, degree of stickiness and a dozen other factors. The consequence is a huge number of varieties, at least 120 000. Botanically the main distinction in *O. sativa* is between *indica* and *japonica* strains. The former are mostly long-grained and photoperiod sensitive, while the latter have plumper grain and mostly are less photo-period sensitive, maturing at a more or less fixed time after planting. (Some systematists also recognize a *javanica* sub-species). Both *indica* and *japonica* rices have existed since very early times, the latter, despite their name, originating in the general vicinity of the Yangtze valley.

Well-developed panicles, even individual seeds, were probably selected as seed-rice from early times. The use of brine to separate good and bad, the former sinking, was well known in China at least four centuries ago. Purposeful selection has resulted in making it possible to grow rice in a great range of environments, most however, having in common the need for growing-season temperatures to be frost-free and over about 20 °C and below about 35 °C, above which crops may suffer heat stress. Nevertheless, some varieties will still grow, though not well, between 4° and 21 °C or at temperatures over 35 °C so long as there is sufficient water. Prior to the era of scientific rice breeding, it is difficult to establish where and when innovations were made. Initial selection for resistance to the stresses of dryness and cold are clearly prehistoric. The same may not be true of tolerance of brackish water for earliest reports come from thirteenth-century China. Perhaps the most important early adaptation, for a short growing-period, was that of Champa rices named for their homeland in Southern Vietnam. These were known to the Chinese by the first century AD. Reaching Fujian before the 11th century, they were taken north to the Yangtze in 1012. Though at first low yielding, but needing only 90 120 days to reach maturity, further selection raised yields. Thus, instead of being a type to be grown when failure of the rains forced late planting, the descendants of Champa rices permitted twice annual rain-fed cropping, a practice widespread in Southern China and Northern Vietnam by about the 16th century.

Selection for survival in deep-water environments is another important process, though its history is obscure. So-called floating rices characterize such environments. As floodwaters deepen, these varieties elongate at the internodes, the plant sometimes lengthening as much as six or seven meters. When the floods recede and the plants touch the ground again, they rapidly go through the final stage of growth before harvest. Such rices are particularly important in Bangladesh and in the back-swamps of Myanmar, Cambodia, Thailand and Southern Vietnam. Similar rices also occur in Mali, Guinea and Sierra Leone. While such deep-flooding areas are a home of *O. perennis*, the evolution of non-shattering but elongating varieties of *O. sativa* allowed the reclamation of such swamps for rice cultivation.

Modern rice breeding was greatly promoted by the Japanese who spread improved varieties, mainly *japonicas*, amongst farmers. Much of their work was based in Taiwan, one notable high-yielding dwarf variety, Taichung Native No. 1, being widely spread in the region and forming a basis for later HYV development. The major impetus to rice-yield improvement came in the 1960s with the realization that Asia s substantially rice-eating population was growing so fast that it was likely to double within 25 years or less. This somewhat belated realization resulted in a strategy of pushing for maximum yields even at the expense of vulnerability to disease and the need for considerable precision in the application of fertilizers, water control and enhanced requirements for weeding, disease and pest control. In a word, the shift was from low input-low output systems of production to high input-high output systems. The plant s architecture was changed from tall to short with the straw having to be stiffened through breeding to carry the additional weight of the larger panicles, a process that forced a change in harvesting methods, especially in Southeast Asia. Varieties were also bred for photoperiod insensitivity and especially, for response to nitrogen inputs, now substantially from artificial fertilizer. At the same time the early HYVs proved susceptible to pests and diseases. For example, the brown plant-hopper, once a relatively minor pest, is now a major one. Much the same is true of tungro virus. The immediate answers have often lain in the application of toxic chemicals, especially organophosphates, one consequence of which has been a reduction in the production of fish, mollusks and crustaceans, once an important component of rice-field ecosystems. While very substantial yield increases have certainly resulted, these have not been without environmental costs, especially the eutrophication of fresh waters. However, later HYVs have been bred for resistance to many of diseases and pests affecting the earlier ones. But generally, environmental requirements are more stringent than for the older traditional varieties.

PRODUCTION SYSTEMS AND ENVIRONMENTAL IMPACTS

The enormous range of production systems, and thus their associated environmental impacts, makes adequate generalization concerning them is difficult. For instance, a study

of system characteristics in Malaysia in the 1960s, before production became much more uniform as a result of the introduction of HYVs, recognized 36 distinct systems, 31 on naturally flat plains or terraces, one on artificial terraces and four on sloping land. Some have disappeared from Asia generally, including rice-based shifting cultivation in mangroves (Myanmar), shifting cultivation involving virgin forest (Southeast Asia generally), permanent brackish-water cultivation in Hong Kong and wet land sowing without clearing or tillage (Peninsular Malaysia).

While production systems are very varied, most fit into the global classification used at IRRI, described by Greenland (1997) and illustrated in Figure 2. This sets out schematically the kinds of environments and topographical positions in which the crop is grown together with approximate areas under each form of cultivation for the early 1990s. Lowland rain-fed and flood systems occupy about a third of the cultivated area but produce only about a fifth of the grain. This is because the water supply is highly variable. The amounts of sediment deposited by flooding are inconsistent and in the deeply flooded areas, plant toxins form through anaerobic conditions. In addition, largely because of farmers uncertainties about the water regime, limited amounts of fertilizer are used. Genetic enhancement of the rice varieties used in rain-fed and flooded areas is also in its infancy, contributing to low yields. Yields range from as low as $1.0\,t\,ha^{-1}$ to as much as $4.0\,t\,ha^{-1}$ in good seasons and favorable locations.

Rice cultivation on dry, sloping land occupies only about a tenth of the total area, yielding a miniscule 4% of global production. Rice grown in such environments, whether by shifting cultivation or semi-permanently, is even more susceptible to dryness. To this may be added weeds, pest problems, especially birds, and a lack of available soil nutrients, especially nitrogen (N) and phosphorus (P).

Irrigation, permitting control of the timing and amount of water, removes or at least mitigates the effects of plant stress through dryness; its provision at the crucial phases of flowering and panicle formation is particularly important. Just over half of the global rice area is said to be irrigated. (Some sources give a lower proportion of about two-fifths.) Of that figure, roughly half again bears two rice crops a year. Consequently almost three-quarters of total production comes from irrigated land. With irrigation, advantage can be taken of higher insolation intensities in the dry season so that grain yields at that time are generally substantially higher than at other times, in California and Australia regularly reaching $10\,t\,ha^{-1}$. Pest and disease pressures are also lower then. Genetic engineering has also produced HYVs well adapted to these controlled conditions, whereas for all other systems, the need for plants tolerance of a variety of unpredictable water conditions has severely constrained rice breeding.

In terms of environmental impacts, a distinction can readily be drawn between those that are associated with the initial transformation of natural ecosystems by clearance and fire and impacts that are the continuing consequences of the existence and intensification of rice-field ecosystems. Not much is known, in biological terms, of what happens when, as in usual, rice replaces forest, especially so far as microorganisms are concerned. Most obvious is a large fall in the standing crop. Where this has been mature forest the phytomass values fall from somewhere in the range of $80\,t\,ha^{-1}$; for light monsoonal forest to about $550\,t\,ha^{-1}$; for well-grown equatorial rain forest to roughly $5\ 15\,t\,ha^{-1}$ of rice plants and associated weeds.

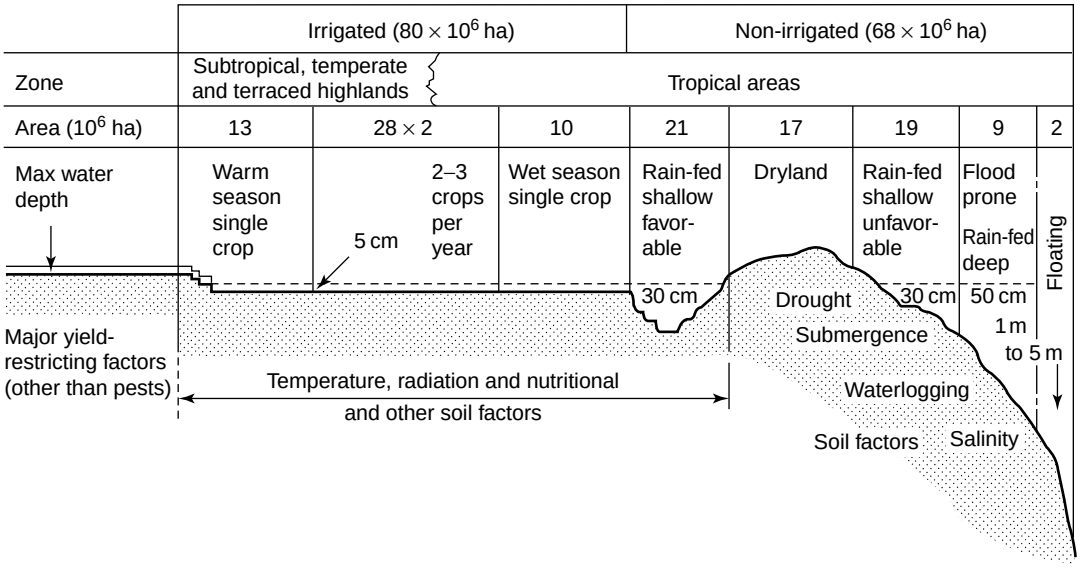

Figure 2 Major rice production systems and areas in 1991 (after Greenland, 1997)

Annual biological production falls less drastically, from 15 30 t ha^{-1} for forest to 5 25 t ha^{-1} for a once-a-year rice crop and its weeds. The amount exported from such systems varies. Where only the grain leaves the eld at each harvest, the range is from 1.0 16.0 t ha^{-1}, though towards the lower end of that span under pioneer conditions as rice ecosystems are being established. The crop residue may remain in place, rot and be recycled, but since this practice tends to lead to a build-up of disease-causing organisms, it is often burnt, releasing CO_2, nitrogen oxides (NO_x), NH_3 and other gases to the atmosphere together with P, K (potassium), (calcium), and Mg (magnesium) to the soil. Where the straw is removed from the eld, similar processes take place in and around farmsteads, rice straw being transformed into combustion products in domestic stoves, into compost as bedding materials for animals or into dung as it is consumed and then recycled onto elds. Increasingly some is used in biogas digesters.

The once-for-all clearance of (usually) forested land for rice unquestionably has added substantial CO_2 and NO_x to the global atmosphere, though since this happened at varying rates in time past it is dif cult to say by how much. Since these gases, bear isotope signatures that permit the identi cation of source, it is possible that fossil air trapped in glaciers and ice caps contains evidence of burning following clearance. This is complicated, however, by the lack of adequate knowledge of the degree to which CO_2 uptake increases in the remaining vegetation. Burning of cleared vegetation certainly releases substantial amounts of nitrogen, estimates for forest ranging from about 100 300 kg ha^{-1}, which may be recycled by washout in rain. Of the other major elements added to the soil, the rice crop takes up a small but vital proportion and larger fractions are lost by eluviation, by volatilization (limited in wet systems) and by sequestration through soil processes. The amounts freed vary in step with the standing crop, up to about 3 t ha^{-1} for mature forest, about half that for well-grown secondary forest and only a few kilograms where the original vegetation is grass.

A particular feature of clearance is a rapid but short-lived ef orescence of soil microorganisms, some of which may be nitrogen- xing. These include actinomycetes, various species of symbiotic and non-symbiotic bacteria, including *Azotobacter* and *Clostridium* spp. as well as the Cyanobacteria, the last being of considerable signi cance where soils are ooded.

Once clearance takes place and a crop or two are taken, the most important consideration is what happens next. On many alluvial soils in rice-growing regions, cultivation is continued, resulting in very different ecosystems from those under natural vegetation. On a few and on slopes, a fallow follows during which natural vegetation regrows and nutrients are restored. This process is more or less rapid depending especially upon the size of the cultivated plot, for regeneration is most rapid at the edges and where there is a plentiful supply of seeds. Regeneration is also in uenced by the period over which rice cropping has taken place since the seeds of some wild plants may survive cropping. What is certain is that *Oryza*, partly because it is a light-loving species, does not long survive the abandonment of cultivation.

Plant succession varies considerably, both from region to region, being in uenced by the regional vegetation and thus the nature of the seed supply and locally depending especially upon the frequency of successive cycles of cultivation. Where the latter is low, woody plants quickly dominate and where a further clearance is long delayed, shade-loving forest species are able to establish themselves. The classical studies of Wyatt-Smith in Peninsular Malaysia in the 1940s showed that within a few years, quick growing trees such as *Mallotus*, *Trema* and *Macaranga* spp. were some 7 10 m high. Beneath them seedlings of true rainforest trees were present, including *Shorea*, *Milletia*, *Durio*, *Koompassia* spp. By contrast, where the cultivation cycle is frequent and fallows short, many invaders are grasses such as *Imperata* and *Paspalum* spp. These are characteristically weeds of cultivation and usually expand their area on abandonment. Should such grass-dominant fallows be burnt, the grasses may form a more or less stable re climax vegetation, returning little to the soil. Where re is kept out, woody species, in Peninsular Malaysia *Macaranga* and *Mallotus* spp. in particular, eventually suppress the grasses, acting as a nursery for more truly forest species.

ECOLOGY

Where permanently cultivated rice- elds are established, the ecosystem is very different. A regular alternation of standing crop, with or without short fallow is established. Over 20 or so years the debris of original clearance nally rots away, a process within ve or so years suf ciently advanced to permit tillage. Where an annual crop is usual, the phytomass increases in a characteristic sigmoid curve from virtually nothing at planting to perhaps 5 25 t ha^{-1} at harvest. It falls away as the crop is cut, rising somewhat as the rice stubble regrows and as weeds invade. In wet systems, as the rice grows, the weeds are suppressed, non-aquatic weeds by ooding and tillage early in the cultivation cycle and aquatic weeds by drying out late in the cycle.

But wet elds are not the only kind to be more or less permanently cultivated. Dryland rice, unlike that grown by shifting cultivation (bush-fallowing), always involves tillage, the crop being grown in unbunded elds depending entirely upon rainfall for moisture. Such cultivation is of particular importance in Latin America and in Africa where, with rice grown by shifting cultivation, dry, upland production accounts for between three-quarters and half of the total rice area. Quite often rice is relay cropped

or intercropped with maize, sorghum, soyabean, peanuts, pulses, manioc, sugarcane, even permanent tree-crops such as coconuts and citrus. (Such systems reduce the incidence of pests and diseases, soil erosion, prevent and provide varied dietary and income sources, reducing vulnerability to drought.) Because of erosion risk and substantially lower grain yields than from wet systems of rice production, permanent dry cultivation is limited to relatively gentle slopes; and where practised without fallows, or added fertilizer. It confined mostly to youthful, nutrient-rich soils especially basic volcanics such as those of Java, Bali and the Philippines.

Not much is known in detail of the ecology of such systems. Certainly the weed-load is much greater than for wet systems, especially as many weeds grow more rapidly than rice in the first two months of the growth cycle. A West African study, for example, showed that weeds reduced grain yield by 33 75% on unweeded wet plots but by 70 100% on unweeded upland plots. The weed communities vary from major region to region, many genera *Echinochloa*, *Ipomoea*, *Cyperus* also being common in lowland wet systems. One major feature however, is the much greater soil loss by erosion on dry, tilled slopes, from which sediment production may be three or four orders of magnitude higher than from lowland or terraced wet systems. Sediment yield is also two or three orders of magnitude higher than from land under the shifting cultivation of rice, where the regeneration of vegetation rapidly reduces erosion unless ineffective grass fallows, such as under *Imperata* spp., follow cultivation.

Little can be said of rice-field communities in general because of a lack of comprehensive ecological studies, though much is known of major plant and animal pests and diseases. Wet rice fields, including those created as artificial swamps on hill-slopes, characteristically contain variable quantities of weeds such as grasses and sedges like *Digitaria*, *Eleusine*, *Cyperus* and *Echinochloa* spp., also wild rice, especially *O. perennis*, and herbs such as *Ipomoea triloba*, in some areas *Chenopodium* and *Amaranthus* spp. themselves furnishing food for man or beast. Floating plants include *Salvinia* and *Nymphaea* spp., and in Asia the American introduction *Eichhornia crassipes*, more important in irrigation systems than in actual fields, as well as free-floating *Azolla* spp., an aquatic fern that in symbiosis with Anabaena fixes valuable nitrogen from the air. In some regions trees may be part of the rice-field ecosystem. From India to Cambodia *Borassus* palms, once a major source of sugar, may grow in the fields, sometimes *Arenga* palms as well. In the fields of Northeastern Thailand, a wide range of trees, both forest survivors and planted ones, is quite common, providing food, medicine, fodder and lumber, all carefully trimmed to avoid excessive shading of the rice crop and consequent depression of yields.

In Northeast Thailand, Heckman noted the presence of 589 animal species, of which 130 can be considered typical rainy season rice-field biota. Another 250 species are common in other habitats but sometimes enter fields. Amongst these are economically important fish, some partly air breathing and capable of surviving the dry season. Common in many lowland parts of Asia are carp (*Cyprinidae*), gouramies (*Trichogaster* spp.), serpent-heads (*Channa* spp.) and catfish (mainly *Clarias* spp.). Yields of such fish vary widely, being very low where toxic pesticides are used. Annual production of 2200 kg $ha^{\bullet 1}$ has been reported from Japan but this seems very exceptional, yields in Taiwan, Malaysia and Tanzania ranging from about 100 kg $ha^{\bullet 1}$ to 300 kg $ha^{\bullet 1}$. Crayfish are locally important, yields of 560 kg $ha^{\bullet 1}$ being reported for Louisiana paddy-fields, while along the Travancore Cochin coast, Southwestern India, prawns are raised during the fallow season, yields ranging from 780 to 2100 kg $ha^{\bullet 1}$ per season.

The most striking remaking of ecosystems for rice cultivation has come about in mountainous areas, notably of South and Southwestern China, especially Sichuan province, in Java and Bali and in the Ifugao region of North-central Luzon, Philippines. In all these regions wet rice terraces are of two kinds. On the one hand, they may be naturally watered by entrapped rainfall, overland flow and to some degree near the bottoms of slopes, by emergent groundwater. On the other hand they receive water from elaborately constructed irrigation systems tapping into the upper courses of small streams and diverting water in a series of carefully controlled cascades falling from one level to the next. Traditionally, both kinds of terrace were confined to lower and middle slopes while the upper slopes acted as gathering grounds for water. Since about 1950, and mainly in South and Southwestern China, the use of mechanical pumps has enabled irrigated terraces to be continued to the tops of slopes, water being recycled several times as a consequence.

The dating of wet terraces is mostly uncertain. Some are thought to be two millennia old. Others are much younger, the early period of Communist rule in China seeing a notable expansion as labor was substituted for capital and local self-sufficiency was encouraged. Construction and maintenance are highly labor-intensive, the former requiring 3000 to 5000 person-days per hectare. Given the recent enhancement of the opportunity cost of labor in wet-terrace areas, there is now virtually no new construction and in some places rice is no longer grown as disintensification takes hold. This may involve the replacement of rice with lychee (*Nephelium litchi*) in upland Guangdong, the growing of sweet potato (*Ipomoea batatas*) rather than rice, or complete abandonment. The last occurred in the 1950s and 1960s in Hong Kong and is now happening in Ifugao, Luzon, where there is concern over the possible loss of a major tourist attraction.

Little is known of the ecology of such artificial vertical swamps, though they are known to contain mollusks and crustaceans, both of some significance as protein sources. Unlike their lowland counterparts, large fish are absent. In addition, there is always the risk of terraces collapsing, despite the usual practice in most areas of facing them with supporting stonework. As in the lowlands, distinctive anthropogenic soils evolve. These are marked (when moist) by a structureless A horizon, often gray in color with reddish mottles, with a marked clay-iron horizon at a depth of about 30 cm. This develops in the course of cultivation and serves to slow infiltration and consequent water loss. Like their lowland counterparts, such rice soils are also high in organic matter, the breakdown of which by various species of Cyanobacteria leads to significant production of CH_4 gas.

METHANOGENESIS

Methanogenesis refers to the making of CH_4, in the case of wet rice fields by a group of Archaebacteria that thrive in the anaerobic environment of the wet fields, as they do in naturally-occurring freshwater swamps. Their significance lies in the fact that CH_4, like CO_2, is a greenhouse gas. CH_4 from various sources may contribute about 15% of the greenhouse effect, compared with roughly 60% from CO_2. When its effects are corrected for decay time (10 years) and for indirect effects, it is said to be 15 times stronger than CO_2 whose decay time is 120 years. Using fossil air trapped in glaciers it has been estimated that global CH_4 levels rose from 0.70 ppm (on a volume basis) in 1787 to 1.68 ppm by 1987, an average rise of roughly 1% a year. Since the mid-1980s, though, the rates have fallen to about 0.5% annual increase (*see* Methane, Volume 1).

Estimates of global CH_4 production and of the proportion contributed by CH_4-producing organisms living in wet rice fields are very varied, reflecting differing methods of analysis, varying assumptions in extrapolating from experimental to global levels and the fact that methanogenesis is highly variable in time and space. A current best estimate is that wet rice fields annually produce $120 \pm 50\ \mathrm{Tg\ yr^{-1}}$ (trillion tons), making up about a fifth of the global production. Stern and Kaufmann indicate a rise of annual production in wet rice fields from 40.1 Tg in 1860 to 101.4 Tg in 1996.

Details of just how certain groups of Archaebacteria produce CH_4 are not entirely clear. In wet rice fields, as elsewhere in nature, a basic prerequisite is the presence in sufficient quantity of appropriate substrates, notably H_2, CO_2 and acetate. The origin of these is not clear – possibly humus, plant residues, autolysates or root exudates. What is clear is that the presence of organic matter increases CH_4 production and that anaerobic conditions are obligatory, for the producers die in the presence of oxygen. The factors responsible for CH_4 production interact in complex and not yet fully understood ways.

Methanogenesis can occur at all temperatures at which rice grows – as well, in nature, at both lower and much higher temperatures. The saturation of the soil with water, giving reducing rather than oxidizing conditions, is essential though a small quantity of CH_4 may be produced in water films around soil particles in some unsaturated soils. Other things being equal, the water regime, both during the period of cropping and during fallow, has major effects. Methanogenesis depends upon a fairly narrow range of negative redox potentials (*see* Redox Potential, Volume 2) and that in turn depends on soil water content. Thus a soil that is wet during fallow is already in a reduced condition whereas a soil initially dry then flooded will not produce CH_4 until several weeks have elapsed. There is some evidence that in such circumstances, even peak production will be lower than in ever-wet conditions. The reasons for this are not altogether clear for not all the CH_4 produced in a field is emitted to the atmosphere. Most is emitted via the rice plants themselves, and probably also by such other emergent aquatic plants as possess gas pathways within their tissues. The remainder that reaches the atmosphere does so by ebullition, bubbling up through the muddy water. But some is consumed, mainly in the root zone, by methanotrophs, organisms using CH_4 to support their metabolism, living in the narrow oxidized zone around every living root. Thus an increase in the number of methanotrophs present reduces emissions so that oxidizing conditions have effects both on CH_4-producing organisms and on CH_4 consumers.

Various management practices clearly affect CH_4 emissions. The growing of forerunner and post rice-harvest crops leads to reduced conditions for shorter periods. Broadcasting seed rice, though leading to lower yields than when seedlings are raised in a nursery and transplanted, is said to reduce the period of inundation required. The application of nitrogen as urea increases CH_4 from some soils but limits its production from others. The use of HCH pesticide (hexachlorocyclohexane) retards CH_4 oxidation, leading to more CH_4 whereas another commonly used rice pesticide, carbofuran, has the opposite effect.

But perhaps the most important consideration, next to water regulation, is organic matter content. Some rice soils, though not good ones, have been developed from naturally organic peats and mucks. Many are developed from alluvium or colluvium. Some, on wet terraces, are developed from sedentary, hill slope soils. Aquatic plants such as *Azolla*, weeds, stubble and even whole rice plants minus their panicles which alone may be harvested, lead to large inputs of organic matter, as much as $8 \pm 10\ \mathrm{t\ ha^{-1}}$ per crop. The bacteria thus have plenty of substrate to live on. In single rice-crop systems, however, post-harvest debris can readily be burnt and though this results in a loss of

nitrogen, the practice leads to less CH_4 output, as does dry fallowing. Ironically, organic farming almost certainly enhances CH_4 output. China s rice production levels are high and are heavily dependent not only upon recycled rice-field phytomass but also on large nutrient subsidies from organics, including pig and human manure as well as compost. It seems likely that China s wet rice fields produce above-average quantities of CH_4 as a consequence.

The prognosis for wet rice-field methanogenesis is circumscribed by data limitations and is thus little better than guesswork. In some places, for example Peninsular Malaysia and Java, wet rice cultivation is being abandoned and not replaced. Where sites remain wet, it seems likely that CH_4 production will continue though at lower levels since vegetation is no longer cut and incorporated into the soil. Where sites dry out, a substantial reduction in methanogenesis is likely. On the other hand, it is clear than in Asia, though not in Africa, clearance of land for new wet rice-fields has substantially ceased. Future increases in rice production, triggered by continuing population growth and possibly also by price rises, may well involve a substantial rise in the area double-cropped with rice. Thus longer periods of flooded, reducing soil conditions and more CH_4 may be expected. This could be partly offset by tighter water control as costs of supply rise and by increased application of artificial nitrogenous fertilizers that may inhibit methanogenesis. Because the decay-period for CH_4 is only about five years, compared with 120 years for CO_2, and because of the much greater global warming potential of CH_4, any reduction in CH_4 production will probably affect the atmosphere quite quickly, diminishing the greenhouse effect.

GLOBAL WARMING AND RICE

Global warming will affect rice production in four ways:

1. Increasing concentrations of carbon dioxide will stimulate plant growth. The effect of this on plant production will depend on whether a species is a photosynthetic C_3 or C_4 type, as well as on the presence of competitors (including weeds) and other factors. This general topic is treated in several articles in Volume 2, although no specific reference is made to rice (*see* C_3 and C_4 Photosynthesis, Volume 2; CO_2 Enrichment: Effects on Ecosystems, Volume 2; Plant Competition in an Elevated CO_2 World, Volume 2; Plant Growth at Elevated CO_2, Volume 2). While early studies, in Japan, indicated increased photosynthesis in rice at levels up to about 500 ppm, above which rates leveled off, later work indicated that at high temperatures, even under low light intensities, increased growth and grain yield occurred at CO_2 levels far beyond what may reasonably be expected globally. Yoshida (1976) suggested that the optimum concentration for growth and yield is in the range 1500 2000 ppm, increases being attributed almost entirely to increased number of panicles. Since this is four to six times current levels it may be concluded that enhanced CO_2 levels would be wholly beneficial. This would certainly be the case for rice yields. But what are not yet clear are the relationships between CO_2 uptake in rice and CO_2 uptake in forests that rice cultivation is still replacing in some parts of the world. The likelihood is that uptake levels for rice are lower than for forest so that land conversion results in enhanced CO_2 levels generally, though matters are much complicated by limited knowledge about uptake by forest species, especially in the tropics, and their response to higher levels of CO_2 in the atmosphere.
2. Warmer temperatures, particularly at night, thus reducing the diurnal temperature cycle. The temperature increases will be highest in polar regions.
3. Changes in the atmospheric general circulation, leading to changes in the strength and timing of ENSO, particularly in the case of Southeast Asia. In its latest scientific assessment (IPCC, 2001), the IPCC is confident that the evidence provided from recent trends and simulation models support the view that the world is warming, and that the warming over the next 100 years will be greater than previously thought (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4). (See also several review articles in Volume 1).
4. Rising sea-level: Unfortunately, data relating rice areas and height above sea level seem not exist. Clearly coastal areas would be vulnerable not merely to higher sea levels themselves but also to the predicted greater frequency of storm surges, bringing salt or brackish water onto coastal fields. Mitigation would include the construction of sea walls, an impossibly expensive option for poor rice-growing countries such as Bangladesh and Viet Nam, and the greater use of salt-tolerant varieties. Unfortunately, these produce less grain than normal varieties. Given that pond production of marine animals is already more remunerative than growing rice, though probably environmentally damaging and unsustainable unless very carefully managed, conversion of use away from rice is probably inevitable in such threatened coastal areas.

Overall, warming could lead to expansion of cultivation into areas currently too cool to permit rice to be grown. In some areas where winter coolness prevents growing a second crop parts of Northern India, central China and tropical uplands generally warming would permit double cropping where only one crop is now possible. Such expansion would be conditional upon water supplies being sufficient to meet increased demands and upon basic economic perceptions amongst farmers. In rice-production

areas where temperatures are already high, and these are around 25 35° latitude, not near the equator, even higher temperatures may depress yields by increasing the incidence of spikelet sterility in the plant and/or by increasing water demand to levels that cannot be met.

SUSTAINABILITY

Given that humankind has been growing rice, sustaining life and high civilizations for several thousand years, it may seem odd to question the long-term sustainability of its cultivation. The fact is that for most of that time yields have been variable from season to season around a mean per crop of roughly 1.0 1.5 t ha^{-1}. By heavy use of organic fertilizer and by close control of the amount and timing of water application, traditional production systems doubled that yield. In rice-based systems of shifting cultivation, where bush fallows were 10 40 years long, yields were probably close to those in most rain fed lowland systems and higher than in some, especially flood-prone ones. The substantial shift to high-input high-output production that began in Western temperate areas in the 1930s and spread rapidly, in Asia especially, in the 1960s and 70s represented a one-way quantum jump to high yields. It would be impossible economically to produce the present amount of rice at the yield-levels prevailing through most of its history. There simply is not enough land. At the same time, it is clear that there are both technological and economic limits to intensification. One straw in the wind here is the abandonment of an experiment at IRRI, Los Banos, which succeeded in annually raising 20 t ha^{-1} of grain by multiple-cropping, optimal water management, varietal choice, fertilizer application and pest control. It was neither technically sustainable nor an appropriate model for ordinary farmers.

Giving details of nutrient balances in pre- and post-1960s cropping system, Greenland (1997) suggests a key role for the nutrients contained in sediments in irrigation water, especially P. These are reduced by sedimentation in the storage-based irrigation systems used in dry areas and dry seasons. However, any macro- or micro-nutrient deficiencies can readily be made up by the continued application of artificial fertilizers, the raw materials for which are likely to be available for some centuries yet. Nitrogen, of course, can readily be fixed from the air using appropriate biological nitrogen-fixers. Their use is not necessarily straightforward. *Azolla-Anabaena*, for instance, requires considerable management skill. *Azolla* readily washes off fields and dies when it is cold or dry. Though at present biological nitrogen-fixation may not be financially competitive with petroleum-derived nitrogen such as urea, the position will improve as the real cost of petroleum products increases. Recycling human urine is technically feasible but suffers from the high cost of concentrating very dispersed sources. Recycling sewage has some of the same problems plus the likelihood of increasing CH_4 as an output from wet fields, plus religious unacceptability in some areas, notably India. Increased nutrient applications will unquestionably lead to increased eutrophication of fresh waters, especially lakes, and near-shore waters. The frequency of damaging algal blooms may increase, while for fresh waters, possible toxicity problems such as excessive nitrate may arise.

Loss of water quality for rice production has already been mentioned but of greater concern is the related question of increasing competition for and cost of water as well as the problems of optimizing its management. The additional amount of water needed by a rice crop depends upon the amount, intensity and timing of rainfall, evaporation, crop duration, soil permeability, and physiological need. Wet field systems need additional water for land soaking to soften the soil aggregates hardened by exposure to sun and thus to allow tillage. According to Greenland (1997), 300 500 mm are needed for land preparation and 540 1620 mm for actual crop growth in systems requiring 100 days from transplanting to harvest with final drainage being initiated 10 days before harvest. Little can be done about rainfall or evaporation. On-field water storage, by raising the height of field bunds is rarely feasible as there is then a risk of drowning the crop, for most varieties have limited tolerance of submergence. Shortening the cultivation period reduces water demand and this can be done by selecting varieties with shorter maturation periods and by direct seeding instead of transplanting. But both alternatives may reduce yields, the former because many short-term varieties produce less grain than long-term varieties, other things being equal, the latter because of increased competition from weeds. Machine tillage also reduces the land-soaking requirement since tractors can handle much more cohesive soil conditions than buffaloes or other traction animals. But costs may increase.

Excess water is also a problem. In dry areas, lack of proper soil drainage readily leads to salinization fatal to rice. In deltaic areas, both depth and duration of flooding are crucial, in relation to crop height, for rice is vulnerable to drowning as just explained. Varieties that elongate when deeply flooded are uniformly low yielding at present so that the breeding of elongating HYVs is a strategic priority for such lands.

Pests, including weeds and disease, continue to be problems, some caused by the very success of enhancing yields. (The cases of tungro and brown planthopper were mentioned earlier). One major concern is that varietal diversity, itself a protection, is being reduced by the use of single varieties over large areas, for each variety has a different pattern of vulnerability to pests. Increase in rice-crop frequency may enable significant pest populations to carry over from one crop to the next. There are well-founded reports of farmers reverting to single annual crops for this

reason. Increasing cropping intensity by using some other crop, preferably a legume to increase nitrogen, is helpful, since many pests are crop-specific. But both insecticides and herbicides may cause major environmental problems, effects upon rice-field animals used as a food source being one example. The use of herbicide has been proposed in mechanized cultivation of rice on sloping land where weed control is a serious problem. But environmental consequences may be rather severe. These may include loss of biodiversity though few studies of this have been undertaken in tropical areas. In these areas generally, it is commonly believed that, other things being equal, pesticide and herbicide use is less damaging than in temperate areas because higher temperatures lead to more rapid chemical breakdown.

A further issue is that of land availability. While it is true that there are significant areas of land that could technically be brought into rice production, even in Asia, it is highly doubtful if such a transformation is economically feasible even if potential farmers value their own labor at close to zero. In the remaining lowland areas, there is competition with forestry, nature conservation, fisheries and a host of other potential uses. In addition, many areas contain soils that are difficult to drain and manage. Such include soils with high levels of organic matter and mangrove soils, in many of which, the cat clays (free sulfuric acid forms on drainage) rendering prolonged flushing with fresh water necessary before planting rice (*see* **Acid Sulfate Soils**, Volume 3). Much prime rice land has been lost forever to urban and industrial expansion, notably in China, the southern province of Guangdong especially, and on the Bangkok plain. Other lands are lost by disintensi cation and abandonment as labor costs rise in relation to prices. Ironically, the latter have fallen in real terms since the 1950s, except for a transitory upward blip in the mid-70s, even as global production has more than doubled. When prices begin to rise once again, as surely they eventually must in the face of continued, though slowing population growth, it will probably again become economic to expand the area under rice. Where production is mainly for self-subsistence, as in many West African rice areas, expansion may still take place even if this is uneconomic at the macro-level. For the rest, intensi cation of production is likely to meet future demand for rice as a result of changes in diet, even though the increase in demand is likely to remain somewhat below the rate of increase of rice-eating populations. What, in detail, the environmental consequences of such intensi cation may be are not entirely clear.

Environmental Change and Human Health: Extending the Sustainability Agenda

A J McMICHAEL

London School of Hygiene and Tropical Medicine, London, UK

Human communities have depleted natural resources and degraded local ecosystems over many years. The usual local consequences have been impairment of health, vitality and social viability. Today, this process is beginning to be played out on a much larger scale, and some of the longer-term consequences for the health of human populations could be commensurately more serious. Today's unprecedentedly large human impact on the environment re ects the great, ongoing, increases in population size and in energy-intensive, high-throughput consumerism. Human-induced changes are becoming evident in the composition of the lower and middle atmospheres, in the worldwide depletion of other natural systems (e.g., soil fertility, aquifers, ocean sheries, and biodiversity in general), and in the disturbances to great natural cycles (especially water, nitrogen and sulfur). These large-scale physical, biological and ecological systems are the source of life-support *upon which the sustained health of populations (human and other) depends.*

The risks to health posed by these global environmental changes are, in many ways, rather different from the well known, locally acting, environmental hazards from direct-acting toxic pollutants. Global change processes are likely to alter the geography of infectious diseases (especially vector-borne diseases such as malaria and dengue, sensitive to changes in climatic conditions and land-use patterns), the productivity of food-producing systems on land and at sea, the availability of freshwater, and, through biodiversity loss, to destabilize and weaken the ecosystems that underpin these and other life-support processes. The depletion of stratospheric ozone poses several direct risks, including increases in skin cancer incidence and the occurrence of eye disorders, and it may also affect immune system activity. Climate change related changes in weather extremes, natural disasters and sea-level rise would have various direct and indirect health consequences. The recently identi ed global dissemination of various Persistent Organic Pollutants (POPs) poses another set of environmental health problems, which may contribute to biodiversity losses in general and to changes in human biological functioning (fertility, reproduction, and immune function).

The spectrum and extent of health impacts from global environmental change will vary around the world. Poor and isolated populations will, usually, be the most vulnerable. Environmental changes and stresses may often coincide, compounding the impact on local human populations. For example, the combined impacts of climate change, freshwater shortages, and land degradation may impair agricultural productivity most in subtropical and semi-arid regions where food insecurity is already prevalent.

The scienti c assessment of actual or potential health impacts faces some unusual dif culties in this complex topic area. There are various types and levels of uncertainties. Many of the systems being studied are complex, non-linear and dynamic. An interdisciplinary research effort is therefore needed that is able to accommodate an unusual mix of complexity, uncertainty and predictive modeling.

There is one particularly important dimension to this topic. These global change processes have major implications for the long-term sustainability of human population health: they may weaken, perhaps irreversibly, the natural life-supporting infrastructure. The widespread, dramatic, gains in health and longevity over the past century have been closely related to the processes of urbanization, social modernization, industrialization and increasing material wealth, as well as to technological advances in preventive medicine, medical care, sanitation and hygiene. Those gains have therefore been associated, to some (uncertain) extent, with the depletion and degradation of our external environment, including most recently larger-scale environmental changes. However, there are likely to be thresholds above which the further use of environmental resources causes no improvement

in health (as is broadly evident from the plateauing of national average life expectancy in relation to per capita gross national product (GNP) at higher income levels). The question arises: given, now, the advent of global environmental change, can we maintain parallel increasing trends in consumption, environmental damage and life expectancy?

INTRODUCTION

Humans, like various other large mammals, are patch disturbers (Rees, 2000). Hunter-gatherers by origin, they have long subsisted in nature by intensive exploitation of a local environment, before moving on to an adjoining virgin patch. Slash-and-burn agriculture is a more structured variant of this behavior. Indeed, among agrarians the principle of rotating crops and leaving land fallow for a season is an extension of this strategy. With variable intensity, and one that usually increases over time as culture and technology evolve, human communities tend to deplete natural resources and degrade local ecosystems. The usual, local, consequences have been malnutrition, impairment of health, conflict, and decreased social viability.

Today, this process is beginning to be played out on a much larger scale, and some of the longer-term consequences for the health of human populations could be commensurately more serious. The scale of human impact on the environment has increased rapidly over the past two centuries, as human numbers have expanded and as the intensity of economic activity has increased. Global economic activity increased twenty-fold during the twentieth century. Meanwhile, in absolute terms, the human population has been growing faster than ever in the last quarter-century, capping a remarkable fourfold increase from 1.6 to 6 billion in the 20th century. While we remain uncertain of Earth s human carrying capacity , we now expect that world population will approach nine billion by around 2050 (*see* Ecological Capacity, Volume 3; Global Population Trends, Volume 3).

Over the past century or so, the typical, localized, symptoms of human environmental impact have been industrial air pollution, urban squalor and chemical pollution of waterways. These local health hazards are now being supplemented with the health risks posed by changes to some of the planet s great biophysical systems and biogeochemical cycles. This includes the climate system, the stratosphere, the hydrological cycle, elemental cycles (especially carbon, nitrogen and sulfur), soil fertility and biodiversity. We are beginning, unintentionally and at a global level, to alter the conditions of life on Earth: even though we remain largely uncertain, even ignorant, of the long-term consequences.

The best known of these global environmental changes is the impact that humankind has begun to have on the composition of the lower and middle atmospheres; the former via the accumulation of heat-trapping greenhouse gases in the troposphere (the lowest 10 km of atmosphere), the latter via the accumulation of ozone-destroying gases in the stratosphere (10 50 km altitude). Other signs of planetary overload include an apparent recent plateauing in the productivity of our main terrestrial and marine food producing ecosystems, a widespread loss of biodiversity, and the global dispersion of various persistent non-biodegradable pollutants (McMichael, 1993; UNEP, 1999). The central issue here is that the underpinnings of human health are being perturbed or depleted. The sustained good health of any population, over time, requires a stable and productive natural environment that yields assured supplies of food and fresh water, has a relatively constant climate in which climate-sensitive physical and biological systems can adapt to short-term and long-term variability, and retains its richness of biodiversity (a source of both present and future value). For the human species, a social animal , the texture and stability of the social environment is also important to population health.

Some of these environmental stresses are likely to cause tensions between human communities, leading to conflict; one of the four biblical Horsemen of the Apocalypse known throughout history as a perennial scourge of population health. For example, Ethiopia and the Sudan, upstream of Nile-dependent Egypt, increasingly need the Nile s water for their own crop irrigation. Around the world, many other river systems are shared uneasily between neighbors in unstable regions: including the Ganges, the Mekong, the Jordan, and the Tigris and Euphrates rivers. Two-fifths of the world s population, living in 80 countries, now face some level of water shortage (Gleick, 1998, *see* Water Use: Future Trends, and Environmental and Social Impacts, Volume 3). Therefore, after the most war-scarred and arms-profiteering century on record, international conflict arising over environmental tensions continues to cast a long shadow over the prospects for human health.

These various global environmental change processes coexist, and share common underlying causes (Watson *et al.*, 1998). They often interact with one another, both in their genesis and their impact (Figure 1). Hence, the net impact of environmental changes upon the health of a population will typically reflect a complex configuration of environmental changes and the synergies amongst them.

A Caveat About the Handling of Uncertainties

Before reviewing the actual or potential impacts of these global changes on human health, it is important to underscore the complex and uncertain nature of the

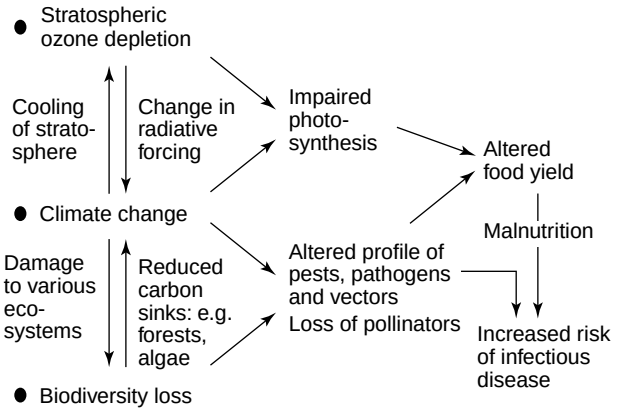

Figure 1 Examples of interactions amongst three global change processes, both in their genesis and in their impacts upon ecosystems and human health

risk assessments being made. The empirical study of single factor toxicity is relatively easy on two counts: first, the scientist can make direct observations of associations (i.e., empiricism), and, second, the assumed causal model is direct-acting and straightforward. Thus, we can calculate the risk of thyroid cancer in children exposed to measured levels of ionizing radiation following the Chernobyl explosion. However, it is a qualitatively different scientific task to assess how the construction of the Three Gorges Dam in China is likely to affect future patterns of vector-borne infectious diseases, since this latter assessment refers to the (non-observable) future and to disturbances of complex, non-linear, dynamic systems and processes.

The task becomes even more complex when the scientist is assuming certain scenarios of climate change for the year 2050 (around which there is inevitably much uncertainty), seeking to model how that will affect (for example) certain species of malaria-transmitting mosquitoes, and then linking that to models of populations with their estimated size, density, age structure, preexisting immunity, nutritional status, and so on. There are various types of uncertainty including, statistical variability (the familiar random variation in a world that is incompletely observed), uncertainties about the sensitivity of the response of particular variables or systems (e.g., mosquito breeding) to a change in an upstream antecedent system (e.g., temperature pattern), and frank ignorance of the identity of all the variables that are actually relevant to the health risk assessment exercise.

GLOBAL CLIMATE CHANGE AND HUMAN HEALTH

The potential impacts of global climate change provides a ready entry point to a more general consideration of the potential health impacts of global environmental change. The Second Assessment Report of the United Nation s (UN s) Intergovernmental Panel on Climate Change (IPCC) (IPCC, 1996) anticipates an increase in average world temperature of approximately 2 3 °C over the coming century (*see* Intergovernmental Panel on Climate Change (IPCC): an Historical Review, Volume 4). This, the report points out, would be more rapid than any temperature increase experienced by humans since the advent of agriculture around 10 000 years ago. Indeed, the most recent analyses of polar ice cores indicate that this would be very rapid warming relative to the global temperature chart over the past 420 000 years (which includes three earlier interglacial periods). Since climatic conditions and climate-sensitive natural processes are an integral part of Earth s life-supporting mechanisms, biologists expect such a change in climate would in uence the prospects for health and survival of many of the species and local populations in affected ecosystems (IPCC, 1996). Likewise, the health of our species, *Homo sapiens*, would be affected.

The various potential health impacts of climate change (direct and indirect, immediate and delayed) are summarized in Table 1 below (McMichael and Haines, 1997). The anticipated effects would be variously mediated via physical, chemical, ecological and social disturbances. Some health outcomes would be bene cial. For example, warmer temperatures would mean milder winters, and this should reduce the seasonal winter peak in deaths that occurs in temperate countries. In currently hot locations, an increase in summer temperatures might reduce the viability of mosquito populations. However, the judgement of scientists engaged in this topic area is that most of the anticipated health impacts of climate change would be adverse (IPCC, 1996). Shifts in climatic means and changes in variability would perturb important physical and biological systems to which human biology, culture and behavior is adapted.

Table 1 Categories of potential health hazards due to global climate change

Thermal stress and weather disasters
Heat waves and cold spells
Floods, storms, droughts, fire
Changes in physical and chemical exposures
Photochemical (and other) air pollutants
Pollens and fungal spores
Freshwater supplies and quality
Changes in ecological systems and relationships
Vector-borne infectious diseases
Water-borne and food-borne infectious diseases
Food yields (land and sea)
Social and demographic disruption
Examples: sea-level rise; impairment/disturbance of agriculture; environmental refugees

The direct health effects of climate change would include changes in mortality and morbidity from heat waves and thermal stress. Climatologists forecast an increase in the frequency of heat waves (because of both the rising mean temperature and a possible increase in weather variability). Some research has indicated that large urban populations in temperate zones, especially in non-coastal locations unbuffered by maritime climates, would experience several thousand additional health related deaths per summer by around 2050 (McMichael *et al.*, 1996). However, relatively little is known about the capacity of human populations to adapt, physiologically and culturally, to such changes across a decadal timeframe. Also, since extremes of heat and cold affect particularly the elderly and the sick, the average life-shortening impact may not be large (Rooney *et al.*, 1998).

Other direct-acting effects would include the respiratory health consequences of altered concentrations of aeroallergens (spores, moulds, etc.) or of air pollutants such as ozone which are produced by temperature sensitive photochemical reactions. The formation of ozone increases markedly as temperatures rise above average summer levels. A change in the tempo of extreme weather events, including storms and floods, would inevitably have a wide range of physical, infectious disease and psychological health consequences.

Of potentially greater consequence are the indirect health effects. Many of these would result from the perturbation of complex ecological systems, including alterations in the range and seasonality of vector-borne infectious diseases; altered transmission of person-to-person infections (including food poisoning and water-borne pathogens); the nutritional and health consequences of regional changes in agricultural productivity; and the various consequences of rising sea-levels. Population health would also be affected by demographic displacements and by regional conflicts over climate-affected shortages of agricultural and water resources.

Vector-borne Infectious Diseases

Changes in patterns of vector-borne infectious diseases would occur because of climatic influences on the vector organisms for diseases such as malaria, dengue fever, the various types of viral encephalitis and schistosomiasis (Martens, 1998). Increased temperatures and altered precipitation would affect the range, proliferation and behavior of vector organisms (e.g., mosquitoes) and intermediate hosts, as well as the viability and maturation rates of the infectious agents within the vector organism. While well-resourced populations in developed countries may be able to maintain public health defenses against an extension (or re-introduction) of vector-borne infections, poorer populations on the margins of endemic areas in tropical and subtropical countries would be at increased risk.

Tropical and Subtropical Regions

Two of the greatest vector-borne disease problems of the tropical and subtropical regions are malaria and dengue fever. Malaria is currently resurging in many countries where it had previously been eliminated or greatly reduced with vector control measures. More than 400 million cases of malaria are estimated to occur annually, including approximately one million (mostly childhood) deaths (World Health Organization, 1999). The *Anopheles* genus of mosquito that transmits malaria has a wide geographic range, that extends through much of the world s temperate zone; as did the disease itself up to the middle of the twentieth century. A malaria crisis is currently emerging in Africa, where poverty is combined with widespread increases in chloroquine resistance in the malarial plasmodium. In India, recent resurgence of malaria has been linked to the combined problems of chloroquine resistance, reduced efficiency of insecticides and the adaptive spread of anopheline mosquitoes into urban areas. The transmission of malaria is increased at warmer temperatures and at higher humidity, and in conditions where surface water is available for mosquito breeding.

Dengue fever is the world s most prevalent vector-borne viral disease, causing an estimated 100 million cases annually in tropical and subtropical countries. Dengue has increased markedly in recent decades, particularly in Central and South America due both to contraction of the earlier mosquito control insecticide spraying programs and to trends in population mobility, urbanization, poverty and regional warming. The *Aedes aegypti* mosquito that is the main vector for dengue is confined geographically by the 10 °C winter isotherm, at around 30° latitude, north and south. Both the intra-mosquito incubation rate of the dengue virus and the biting rates of the *Aedes aegypti* mosquito increase markedly at warmer temperatures.

Other tropical vector-borne infectious diseases that are known or likely to be sensitive to changes in climatic conditions are schistosomiasis (or bilharzia, spread by water-snails), leishmaniasis (spread by a sand fly), onchocerciasis (river blindness, spread by the black fly), and perhaps yellow fever (spread, like dengue fever, by the *Aedes aegypti* mosquito).

Recent analogue studies of malaria in Zimbabwe, Rwanda and Ethiopia have used natural climate variability to foreshadow aspects of future climate change impacts on health (Patz *et al.*, 1996). Those studies indicate that future warming would very probably cause malaria to move to higher altitudes and thereby affect currently unexposed highland populations. Other recent analogue studies have confirmed the sensitivity of both malaria and dengue to inter-annual climatic variations, especially those associated with the El Nino La Nina cycles (Bouma and Dye, 1997; Hales *et al.*, 1999). Interestingly, there have been reports

of recent upwards movement of malaria, dengue fever, or their mosquito vectors in several continents, in conjunction with glacier retreat and alpine plant ascent (Epstein *et al.*, 1998).

Simulation with integrated mathematical modeling, for standard scenarios of climate change, project that the geographic range of potential malaria transmission would undergo a net expansion (Martens, 1999). An additional 4 6% of the world s people (i.e., several hundred million people) would be at risk of malaria, depending on the assumed extent of climate change. Similar mathematically modeled projections have been made for dengue fever and schistosomiasis. While the models show that the geographic range of potential transmission of dengue fever would increase under the climate change scenarios, global warming is likely to lead to a diminution in the geographic range of transmissibility of schistosomiasis because the warming of water would reduce the viability of certain major species of water snail.

It must be emphasized that these global level models necessarily gloss over many regional differences in microclimate, local ecological relationships and biological differences between species of vector mosquitoes or snails. However, in future, with sufficient local detail and with greater computing power, it will be possible to apply this type of mathematical model at higher resolution to local conditions. The models provide estimates of the *potential* transmission of these diseases. The actual incidence of infection would depend on preexisting defenses (such as surveillance systems, environmental management, and rapid case treatment) and on how the populations respond to changes in risk.

Temperate Zone

Various vector-borne infectious diseases that occur in temperate regions are also sensitive to meteorological conditions. Such diseases are likely to undergo changes in patterns of occurrence under conditions of climate change. The diseases include:

1. Tick-borne viral encephalitis: This infection, which occurs in parts of Western Europe and Scandinavia, appears to be sensitive to winter seasonal temperature. There is some evidence that warming over the past two decades has caused this disease to increase its geographic range northwards in Sweden (Lindgren, 1998).
2. Leishmaniasis: This infection, shared by dogs, foxes and humans and spread by infected sand flies, is endemic in the rural Mediterranean region of Europe and in the eastern Mediterranean. Modeling studies indicate that climate change may extend the habitat of the sand fly vector northwards. The disease has been reported, anecdotally, in dogs and foxes at higher altitudes in the European Alps in recent years.
3. Lyme disease: This infection is caused by the spirochete *Borrelia burgdorferi* (McMichael *et al.*, 1996). It is transmitted in Europe and North Eastern USA by the infected tick *Ixodes ricinus*, and has been apparently increasing in incidence in at least the USA in recent decades. Temperature influences the tick s three-stage lifecycle (larvae, nymphs, adults) and, hence, the probability of tick infection by the spirochete. Very high temperatures reduce the survival of ticks. Land-use patterns and climatic conditions influence the density of other mammalian hosts to the tick, such as rodents and deer.

Person-to-person Infectious Disease

Climate change would also influence various directly transmitted infections, especially those due to contamination of drinking water and food, many bacteria and protozoa sensitive to temperature. Further, changes in the pattern of rainfall can disrupt surface water configuration and, hence, drinking water supplies. Hence, the occurrence of infectious diseases such as cryptosporidiosis and giardiasis, spread via contaminated drinking water, would be influenced by a change in climatic conditions. It is therefore relevant to note that rainfall intensity increased in the USA during the twentieth century (Karl *et al.*, 1995).

Research findings suggest, increasingly, that the spread of cholera is facilitated by warmer coastal and estuarine waters and their associated algal blooms. Recognition of this necessitates a revised transmission model of cholera: we must add an ecological dimension. Transmission is not simply person-to-person via the direct fecal contamination of local drinking water. Detailed electron microscopic studies have indicated that the tiny phytoplanktonic (algal) and zooplanktonic organisms (the base of the marine food web) act as a natural environmental reservoir, and amplification system, for the cholera bacterium (Colwell, 1996). There is now evidence indicating that the seasonal or inter-annual warming of coastal water around the coasts of Peru and Bangladesh facilitates the entry of cholera into the coastal communities. Further, this effect is probably heightened by the eutrophication of coastal and estuarine waters that occurs because of the increased loads of human-produced phosphates and nitrates in surface water and wastewater runoff.

Food Production, Hunger and Malnutrition

Yields of food, especially cereal crops, are sensitive to temperature, rainfall, and soil moisture. Climate change would result in regional gains and losses, reflecting the local balance of changes in temperature, soil moisture, carbon dioxide fertilization, and alterations in crop pest and pathogen activity (Rosenzweig and Hillel, 1998). Modeling studies consistently indicate that tropical and subtropical

countries would be negatively affected (Rosenzweig and Hillel, 1998). Further, many communities reliant on traditional agriculture may lack the resources and adaptability to switch to alternative crops and production methods. Although some mid-continental drying in summer months would occur in North America and Europe, high latitude temperate zones (e.g., Canada and much of Siberia) might gain in agricultural production. With longer-term continuation of climate change, however, the net impact upon world agriculture may be negative.

Poor and economically disconnected populations, unable to offset reduced yields via trade, would be most severely affected by reductions in local food production. Hunger and malnutrition increase the risk of infant and child mortality and cause physical and intellectual stunting. Energy levels, work capacity and health status are reduced in adults. One pioneering modeling study estimated the additional number of hungry people attributable to standard projections of climate change (as defined by the IPCC) by the year 2060, within a range of plausible future trajectories of demographic, economic and trade liberalization processes (Parry and Rosenzweig, 1993). The estimate varied, depending on the mix of other assumptions, between an additional 40 million and 300 million relative to a future background total of around 600 million hungry people. Subsequent modeling by Parry and colleagues, using updated climate inputs, indicates a figure of around 70 million by the 2080s, this figure reduces by approximately one half if greenhouse gas emissions are constrained to stabilize at around 550 750 ppm (Parry *et al.*, 1999).

Water supplies, an essential input to agriculture, animal husbandry and personal hygiene, may also be adversely affected by climate change in many regions. Tensions over freshwater shortages, especially in low-to-middle latitude locations where adjoining countries share river basins, would be exacerbated by changes in rainfall. Conflict and public health adversity might then result.

Sea-level Rise: Effects on Coastal Regions and Populations

Sea-level is forecast to rise by approximately 40 cm by 2100 (IPCC, 1996). This rate of rise would be several times faster than over the past century. Its importance derives from the fact that over half of the world s population lives within 60 km of the coast. Sea-level rise may affect various processes and structures upon which our food production, freshwater supplies, economies and public health depend. However, because sea-level rise is a relatively slowly occurring physical process, protective action should be possible in many coastal regions.

Some of the world s coastal arable land would be damaged by sea-level rise, via salination and erosion. Rising seas would salinate freshwater aquifers, particularly under small islands, and may cause sanitation problems for coastal populations. The 10 countries most vulnerable to sea level rise include Bangladesh and Egypt, with huge river delta farming populations, Pakistan, Indonesia and Thailand, all of which have large and relatively poor coastal populations.

A particular public health hazard would arise if small island populations and coastal populations in poor, populous countries with few material resources were displaced. A half meter rise (assuming today s population) would approximately double the number who experience flooding annually, currently around 46 million. Sea-level rise would also affect sewage and wastewater disposal, the physical safety of coastal structures, the viability of coral reefs, mangroves and wetlands (fish nurseries), and the ecology of certain infectious diseases (e.g., malaria and cholera). Sea-level rise, ocean warming, and alteration of currents and nutrient flows would all contribute to changes in marine ecosystems. The health related consequences of these disturbances include algal blooms (implicated in cholera transmission) and the production of toxins, such as ciguatera, in edible fish and shellfish.

STRATOSPHERIC OZONE DEPLETION, ULTRAVIOLET RADIATION AND HEALTH

Stratospheric ozone depletion is essentially a separate phenomenon from greenhouse gas accumulation in the troposphere. It is primarily caused by the buildup of human-made ozone-destroying gases in the stratosphere, such as the chlorofluorocarbons (used in refrigeration, insulated packaging and spray-can propellants). The resultant increase in UltraViolet Radiation (UVR) exposure is expected to peak within the first two decades of the 21st century and then to decline, in response to the substantially successful phasing out of the major ozone-destroying industrial and agricultural chemicals. The concentration of stratospheric ozone, and its ultraviolet shielding effect, should return to normal levels by around 2050.

For at least the first two-thirds of the twenty first century, we can expect the ongoing increase in UVR exposure to augment the severity of sunburn, the incidence of skin cancers, and the incidence of various disorders of the eye (especially cataracts). It could also cause some suppression of immune functioning, thus increasing susceptibility to infectious diseases and perhaps reducing vaccination efficacy (UNEP, 1998). Another potentially important, though indirect, health detriment could arise from ultraviolet-induced impairment of photosynthesis on land (terrestrial plants) and at sea (phytoplankton). Although such an effect could reduce the world s food production, few data are yet available.

Destruction of stratospheric ozone is continuing, and increases in ground level UVR flux are presumed to

have occurred, particularly at higher latitudes and altitudes (UNEP, 1998). The approximate estimates of increases in biologically active radiation (i.e., the UV band which causes skin reddening) in the 1990s, relative to the 1970s, are:

- Latitude 40 50 °N: 7% in winter/spring; 4% in summer/fall;
- Latitude 40 50 °S: 6% on a year round basis;
- Antarctic: 130% in spring;
- Arctic: 22% in the austral spring.

Skin Cancer

Most interest has centered on an expected increase in the risk of skin cancer. Epidemiologists have firmly established that solar radiation exposure increases that risk. However, the relationship differs according to the type of skin cancer.

Non-melanotic skin cancers are of two major histological types: basal cell carcinoma and squamous cell carcinoma. The risk of these cancers has generally been thought to correlate with cumulative lifetime exposure to solar radiation. However, recent evidence suggests that the relationship is more complex, at least for basal cell carcinoma, for which it appears that childhood exposure may be important. It has, accordingly, been estimated that persistence of the level of ozone loss experienced over the past decade or two would cause the subsequent annual incidence of basal cell carcinoma (the dominant type) to increase by 1 2% at low latitude (5°), 14% at 55 65° in the Northern Hemisphere (e.g., the UK), and 25% at that latitude in the Southern Hemisphere. The estimated percentage increases for squamous cell carcinoma would be approximately twice as great.

Malignant melanoma occurs much less often than the other two types, but it is much more likely to be fatal. The relationship between malignant melanoma skin cancer and UVR is complex. Overall, 60 90% of melanomas in fair-skinned populations are estimated to involve sunlight exposure. Repeated sunburn episodes in early life are thought by epidemiologists to be important for the development of melanoma.

The most recent assessment by the United Nations Environment Programme (UNEP) (UNEP, 1998) has updated the above projections for total skin cancer for a European (i.e., fair-skinned) population living around 45° North. Under the amended Montreal Protocol there will be an estimated excess incidence that peaks at around 5% during the third quarter of the 21st century. This entails an extra 100 cases of skin cancer per million population per year due to stratospheric ozone depletion, relative to the current background rate of skin cancer of approximately 2000 cases of skin cancer per million population per year. If the moderate aging of the European population is factored into the modeling, the excess incidence becomes, proportionally, a little higher. These calculations assume, for the sake of simplicity, that behavioral and other risk factors do not change, and that current ozone depletion rates and UVR exposure increases are sustained during the next several decades. Darker skinned populations would be affected less, both because of their lesser susceptibility to skin cancer and because the changes in ambient UVR levels are less at lower latitudes.

Ozone Depletion, Ultraviolet Radiation and Damage to the Eye

Exposure to UVR can also damage the tissues of the eye. The condition most directly linked to UVR exposure is corneal photokeratitis (snow blindness), which is caused by acute exposures and is the ocular equivalent of sunburn. Chronic exposure to UVR also contributes to conjunctival conditions such as pterygium (UNEP, 1998). The role of UVR in the formation of cataracts (opacities in the lens) remains complex and unclear. Some types of cataract appear to be associated with UVR exposure, while others do not. Since cataract accounts for a majority of the tens of millions of cases of blindness in the world, even a marginal impact of increased UVR exposure on their occurrence would be significant.

Ozone Depletion, UVR and the Immune System

There is evidence from both humans and experimental animals that UVR causes both local (i.e., occurring only at the site of irradiation) and systemic (body wide) suppression of immune system activity. The familiar effect of solar exposure on herpes simplex infection (cold sores) attests to the immunosuppressive effect of UVR. The consequences of immunosuppression for human health, particularly for susceptibility to infectious disease in human populations, are uncertain but potentially important.

UVR-induced changes in immune response may also affect autoimmune diseases. Increase in UVR may either suppress or aggravate the disease depending on the type of immune response that underlies the pathology. It has recently been proposed, on the basis of epidemiological and laboratory evidence, that increased levels of ambient UVR exposure are associated with decreased occurrence of multiple sclerosis. This may account for the otherwise unexplained strong positive correlation between latitude and prevalence of multiple sclerosis. UVR is known to aggravate lupus erythematosus, another autoimmune disorder, when used as a medical treatment (UNEP, 1998).

LAND DEGRADATION, OCEAN FISHERIES AND FOOD YIELDS

Land degradation and the loss of topsoil have become a worldwide problem in recent decades. During the 1980s, the

combination of erosion, desiccation and nutrient exhaustion, along with irrigation-induced water-logging and salination, rendered unproductive one-fifteenth of the world s 1.5 billion hectares of readily arable farmland (World Resources Institute, 1998; UNEP, 1999). The world s per person production of cereals, the main source of dietary energy, seems to have faltered a little since the mid-1980s (Kendall and Pimentel, 1994). It is not easy to assess to what extent this reflects a decline in the productive resource base. Other political, economic and consumer trends have also influenced patterns of world agriculture (Dyson, 1999). Nevertheless, the Green Revolution , which fed much of the expanding Third World population during the 1960s to the 1980s, depended greatly on the combination of laboratory-bred high-yield cereal grains, fertilizers, groundwater and arable soils. In retrospect, the productivity gains of the Green Revolution are assessed to have come, in part (and probably substantially) from the exhaustion of natural resource capital, especially depletion of topsoil and groundwater (*see* **Green Revolution**, Volume 3).

Meanwhile, at sea, many of the world s great sheries are now on the brink of being over-exploited (*see* **Changes in World Marine Fish Stocks**, Volume 3). The UN s Food and Agricultural Organization estimates that we have neared the sustainable sh-catch limit: around 100 million tones per year (Food and Agriculture Organization, 1995). Although yields from aquaculture are increasing, it faces some unusual ecological dif culties, with problems of water pollution and infection of the farmed sh. Further, it is much less energy ef cient than agriculture since plant or animal feed stuffs (compared to sunlight!) are needed as the energy inputs.

Today, as we continue on the treadmill of having to extract greater food yields to feed ever more people, almost one-tenth of the world population is malnourished to an extent that impairs health. The *absolute* numbers of malnourished persons in the world, especially children, are still growing. This longstanding problem is today being exacerbated by the rapidly widening disparity between rich and poor: evident in the contrasting trends of widespread continuing hunger and steady increases in the prevalence of obesity in urban populations everywhere.

LOSS OF BIODIVERSITY, AND SPREAD OF INVASIVE SPECIES

An increasingly pervasive problem is the worldwide loss of biodiversity: the loss of species, strains and local populations and, more serious, the weakening or collapse of ecosystems when key species disappear. Through our own species spectacular reproductive success and our energy-intensive economic activities, we have occupied, damaged or eliminated the natural habitat of many other species. Biologists estimate that this fastest-ever mass extinction may cause around one third of all species alive last century to be gone before the end of the twenty- rst century (Soule, 1991; UNEP, 1999). The adverse consequences of the loss or weakening of whole ecosystems would include reduced yield from natural and managed food producing systems and disturbances of the ecology of various vector-borne and other infections.

A continuing loss of biodiversity will forfeit a rich repertoire of genetic and phenotypic material. In particular, our major cultivated food plants are selectively enhanced descendants of wild strains. To maintain their hybrid vigor and environmental resilience, a diversity of wild plants needs to be preserved as a source of genetic additives. Similarly, a high proportion of modern medicinal drugs in western medicine has natural origins, and many defy synthesis in the laboratory. Scientists test many thousands of novel chemicals from nature each year, seeking new drugs to treat HIV, malaria, drug-resistant tuberculosis, cancers, and so on.

About one quarter of all Western medicines and pharmaceuticals come from plants and another quarter from animals and microorganisms. This includes analgesics, antibiotics, tranquilizers, diuretics, steroid contraceptives and anti-cancer drugs. Their annual commercial value is around US$40 billion. Myers has calculated that the usual hit rate in the bioprospecting of tropical plant extracts for new medicinal drugs is of the order of 10^{-5} to 10^{-6} (Myers, 1997). Therefore, the as yet unprospected extracts (estimated at 750 000, each of which could be screened about 500 ways for different properties) should yield at least 375 new drugs. This compares with the 48 in current use (including curare, quinine, codeine, pilocarpine and the life-saving cancer treatment drugs vincristine and vinblastine). This simple arithmetic suggests that ve-sixths of tropical vegetative nature s medicinal goods have yet to be recruited to the bene t of humankind.

But nature s medicine chest is much larger than that. From the animal kingdom come many promising compounds, secreted by frogs (antimicrobials and potent painkillers), sea-urchins, crustaceans, barnacles and many others. Presumably some simple arithmetic could be done here, too, that would underscore the immense option value of these as yet undiscovered, unused, goods.

Closely related to the loss of species is the introduction of invasive (non-indigenous) species into distant, unrelated, ecosystems. This process is accelerating in today s world as a result of chance, ignorance or human folly, combined with the global escalation in human mobility and trade. Invasive species can affect human health via several pathways (McMichael and Bouma, 2000). Changes in the continental range and incidence of human infectious disease is the major, age-old, example. Other introduced species that impair food yields (pests, pathogens, weed competitors, or herbivores such as rabbits in Australia), food storage

(moulds and pests such as rodents and sparrows) or that produce food-borne biotoxins (various species of aquatic algae and toxin producing moulds) also pose risks to human health.

The new fluidity in patterns of human infectious disease that has been evident over the past several decades provides a clear signal that ecological opportunities and physical dissemination pathways for microbes are increasing in the contemporary world (Wilson, 1995). The geographic range of many human infectious diseases has increased with recent changes in patterns of land use and regional climate. Intercontinental trade and rapid long-distance human mobility have introduced various pathogens into distant populations. Some of the more dramatic examples include the introduction of the Asian tiger mosquito (*Aedes albopictus*, which spreads dengue fever and yellow fever) to the Americas, Africa and South East Europe, the reintroduction (after a century of absence) of the cholera bacterium to South America, and the spread of the life-threatening *Escherichia coli 0157* bacterium in meat exports. Meanwhile, antibiotic-resistant bacteria (e.g., tuberculosis, staphylococci, enterococci), a special type of invasive variant, are now becoming a widespread problem for human health (*see* Biological Invasions, Volume 2).

PERSISTENT ORGANIC POLLUTANTS (POPs)

We are by now very familiar with the occurrence of local toxic chemical hazards from environmental pollution of air, water, soil and food. They are the continuing focal point of most public concern about environmental hazards. However, it is becoming clear that there is another, potentially serious, dimension to this problem: many organic chemical pollutants are stable and persistent and, as their entry into the environment builds up, they are tending to disperse more widely. This, of course, has long been the case for non-biodegradable heavy metals, such as lead, and perhaps for long lasting radioactive elements, such as strontium-90. But we have recently learnt that various semi-volatile organic chemicals are readily spread from low to high latitude, via atmospheric global distillation processes, and that they may consequently achieve higher environmental and biotic concentrations at those higher latitudes (Harner, 1997). In recent years the concentrations of bioaccumulated toxic chemicals in fish eaten by the Inuits has increased.

There is therefore, today, a heightened concern over compounds such as dioxins, dichlorodiphenyltrichloroethane (DDT), the polychlorinated biphenyls (PCBs), toxaphene, dieldrin and hexachlorobenzene (Watson *et al.*, 1998; UNEP, 1999). These accumulate in the fatty tissues of many organisms, particularly predators at the top of the food chain. There is suspicion that several of these compounds may cause birth defects or cancer in humans. Some of them are known to interfere with the normal functioning of mammalian, bird and fish organ systems: the reproductive system, the immune system and the central nervous system. Many examples of damage to wildlife have been documented, including declines in bird populations due to eggshell thinning, the poisoning of aquatic organisms, and the apparent suppression of immune function in seals.

It is not yet clear what health effects from these exposures might be occurring in human populations. Insidious effects on intellectual functioning, on fertility, or on immune activity are not easy to detect in epidemiological studies. Nor, yet, has much direct evidence been sought of changes in indices of human biological function in association with exposure to POPs. There is some suggestive evidence of a decline in the density and quality of male sperm over the past half-century, which could reflect the impact of environmental endocrine disrupting chemicals (Sharpe and Skakkebaek, 1993). However, this remains a contentious issue.

TRADE, LAND-USE, ECONOMIC DEVELOPMENT AND INFECTIOUS DISEASES

In the 1950s, René Dubos pointed out that technological innovation, whether industrial, agricultural or medical, disrupts natural ecological balances and unleashes infectious diseases (Dubos, 1959). During the third quarter of the 20th century, as the Western style model of economic development was urged upon all non-communist Third World countries, it became clear that large-scale human interventions in the natural environment often, and usually adversely, affected infectious disease patterns. During the 20th century, large development projects such as dams, irrigation schemes, land reclamation, road construction and population resettlement programs (as is currently occurring in Indonesia) have often potentiated the spread of diseases such as malaria, dengue, schistosomiasis and trypanosomiasis. Such large-scale developments in the Eastern Mediterranean, Africa, South America and Asia have been consistently associated with increases in communicable diseases, especially schistosomiasis and filariasis (which includes elephantiasis). However, because changes in land-use patterns are typically accompanied by changes in population density, population mobility, pesticide usage, and regional climate, it is difficult to assign specific causal explanations. Indeed, many of the health outcomes result from interactions between these various change processes.

Long-distance shipping apparently introduced the cholera bacterium into Peruvian coastal waters in 1991, causing the first outbreak of cholera in that continent for nearly 100 years (Colwell, 1996). The inoculation coincided with unusual warming of coastal waters and extensive algal blooms at the inception of an El Nino event. Similarly, in the 1980s, intercontinental trade in used car tires introduced the East Asian mosquito vector dengue fever, *Aedes*

albopictus, into South America, the Southern USA and Africa. At about the same time, the mosquito vector for Ross River virus disease, *Anopheles camptorhyncus*, probably reached New Zealand on a ship that transports pine wood across the Tasman Sea between New Zealand and Australia.

Modern patterns of human labor, touristic mobility and sexual networks potentiated the spread of HIV from a quiet backwater in central Africa. Other aspects of modern human ecology (the rapid worldwide urbanization, intensification of food production and distribution systems, and various clinical and recreational exchanges of blood and other tissues between human individuals) are all opening new doorways for microbial traffic.

Land Use Patterns and Infectious Disease

Land-use patterns influence patterns of infectious diseases. As population pressures increase, more forest and other virgin land is cleared for agricultural and pastoral purposes. The composition of vector species generally changes following changes in environmental conditions. For example, deforestation in the Indo-Australian region has enabled malaria-transmitting *Anopheles punctulatus* species to become established. In contrast, several *Anopheles* species (including *Anopheles dirus* in Thailand and *Anopheles darlingi* in South America) have disappeared following deforestation that removed the flora and fauna upon which they depended.

Forest clearance in South America during recent decades, to extend agricultural land, has mobilized various viral haemorrhagic fevers that previously circulated quietly (and generally benignly) in wild animal hosts. For example, the Junin virus, which causes Argentine haemorrhagic fever, naturally infects wild rodents (the mouse, *Callomys callosus*). However, extensive conversion of grassland to maize cultivation in recent decades stimulated a proliferation of this species of virus-bearing mouse, thus exposing human farm workers to this new virus. In the past 35 years, the land area carrying this new human disease has expanded seven-fold and the average annual number of infected persons is of the order of several hundred, up to one-third of whom die (WHO, 1997). Likewise, other new viral infectious diseases in rural South American populations have been caused by the Machupo virus, Basia virus, Oropouche fever, and so on. In South America, leishmaniasis (spread by sand flies) is now widely considered an occupational disease of forest workers engaged in land clearance for agriculture, road building, timber extraction, or mining.

Ongoing land clearance in other populous regions of the developing world, and the extension of irrigation, continue to influence the patterns of infectious diseases. In the Sudan, for example, schistosomiasis appeared within several years of the start of the Gezira Scheme to irrigate cotton production; simultaneously, the prevalence of malaria also increased markedly in this region. Dam building and extensions of irrigation also affect the geography of malaria and other mosquito-borne infections. For example, outbreaks of Rift Valley Fever occurred in the Nile Valley in 1977 and in Mauritania in 1987 following the damming of major rivers. In Senegal, the irrigation of rice and sugarcane agriculture that followed the construction of the Diama Dam on the Senegal River caused a massive outbreak of schistosomiasis (WHO, 1997). Similarly, the building of the Aswan dam on the Nile River resulted in a seven-fold increase in schistosomiasis in the local population. Lymphatic filariasis in the southern Nile Delta has increased 20-fold in prevalence since the 1960s, primarily due to the increase in breeding sites for the mosquito *Culex pipiens* following the rise in the water table caused by extensions of irrigation. The situation has been exacerbated by increased pesticide resistance in mosquitoes due to heavy agricultural pesticide use and by rural-to-urban commuting among farm workers.

Other aspects of land use also contribute to the generation of new or amplified infectious disease agents. An example of the production of new variants of infectious agent is that of the influenza virus. This virus has its origins in birds. As the number and density of co-habiting farmers, ducks and pigs in southern China increases, so do the probabilities multiply of creating and launching new genetic recombinants of the influenza virus. Pigs infected by multiple strains of avian influenza virus act as genetic mixing vessels, yielding new recombinant deoxyribose nucleic acid (DNA) viral strains that may then infect the pig-tending humans (*see* Infectious Diseases, Volume 2).

Changes in patterns of rainfall, runoff and surface water movement would have implications for the volume and quality of freshwater supplies. The deforestation of hillsides exacerbates the runoff of rainfall, causing flooding in the short term and reduced water availability in the medium term. In some regions, including current semi-arid regions, rainfall may decline because of climate change; in other regions rainfall is forecast to become more intense. Flooding and overloading of wastewater systems would often contaminate freshwater supplies: as occurred in Tajikistan, in 1994, when unusually heavy rainfall overwhelmed the urban sewage system, causing an outbreak of typhoid fever.

URBANIZATION AND HEALTH

An integral part of globalised changes in the world environment is the spectacular shift of human populations into cities. Humans now appear to be destined to become an urban species. The urbanised proportion of the world s population has grown from around 5 to 50% in the past two centuries, and is still rising. This urban migration reflects,

variously, the advent of industrialization, the contraction of rural employment, the flight from food insecurity and other forms of insecurity, and the search for jobs, amenities or stimulation.

This massive urbanization is occurring in a world that is, today, changing rapidly on many fronts: economic, social and environmental. Today s world is one in which local urban employment opportunity is affected, often abruptly, by global free market forces; in which the sprawling growth of slums and shanty towns is an expression of persistent and markedly widening economic inequalities. As a result the spread of new and resurgent infectious diseases is facilitated by unhygienic conditions, intensified patterns of human contact (sexual and other), regional environmental change and ecological disruption, and rapid human mobility and long-distance trade.

The urban environment, physically, confers various benefits upon human health and wellbeing. There is readier access to health services, education, financial and social services. The urban environment is stimulating, open, and rich with new opportunities. Yet big cities are often unfriendly, impersonal, and sometimes menacing. Noise, traffic congestion and residential crowding are stress inducing. The air quality is poor in cities around the world, particularly in many of today s large Third World cities. An estimated 130 000 deaths and 50 70 million incidents of respiratory illness occur each year due to episodes of urban air pollution, half of them in East Asia (WHO, 1997). An even greater toll of chronic disease is attributable to long-term exposures to air pollution. Third World urban populations, particularly the very poor in slums and shantytowns, also face the hazards of unsafe drinking water, solid waste accumulation and toxic wastes (*see* Urban Poverty and Environmental Health, Volume 3).

Urban Transport

The density of private cars in the world s cities is escalating rapidly. In large part this reflects the unplanned and uncontrolled domination of urban transport systems by roads and cars in a world in which national governments have become increasingly beholden to free-market orthodoxy and in which transnational corporations (including car manufacturers and petrochemical companies) assume increasingly powerful, global, influence. Currently, we appear to have little vision of an urban future that is not dominated by privately owned vehicles. Accordingly, traffic congestion now characterises cities nearly everywhere: although the past decade has seen the beginnings of a swing back to light rail (especially tram) systems in many European and some US cities (Newman and Kenworthy, 1999).

In addition to the fragmentation of neighbourhoods, intrusive noise, and restrictions on physical exercise, there are three broad categories of public health hazard from this burgeoning urban car traffic:

1. Fatal and non-fatal injuries of car occupants, pedestrians and cyclists. Over three-quarters of a million deaths from road crashes occur annually, the great majority of them in developing countries.
2. Exhaust emissions that cause local air pollution, particularly photochemical smog during summer months. Urban air pollution has, in recent decades, become a worldwide public health problem. In China, urban air pollution with particulates and sulfur dioxide is increasing sharply in association with rapid industrialization and the proliferation of automotive vehicles. The main source of pollution is the industrial use of coal, with its relatively high sulfur content. However, emissions from domestic cooking and heating fuels are also increasing. Morbidity and mortality in Chinese cities is expected to increase steeply over the coming two decades.
3. Exhaust emissions that contribute to acid rain and to the global accumulation of the greenhouse gas carbon dioxide, each of which has wider ranging consequences for human health. In developed countries, traffic exhaust gases account for around one quarter of national greenhouse gas emissions.

Heatwaves, Urban Vulnerability and Mortality

Severe heat waves adversely affect health. It is very likely that the frequency, if not the intensity, of heat waves will increase in the 21st century as world temperatures rise. Obversely, some temperate-zone populations will experience an amelioration of winters, with fewer periods of severe cold. The mortality impact of heat waves is typically greatest in the centers of large cities, where not only do temperatures tend to be higher than in the leafier suburbs and the surrounding countryside, but the relief of night-time cooling is lessened. This heat island effect is due to the large heat-retaining structures and treeless asphalt expanses of inner cities and the physical obstruction of cooling breezes (*see* Urban Heat Island, Volume 3).

In July of 1995, in the USA, more than 460 extra deaths were certified as due to the effects of the extreme heat wave in Chicago when temperatures reached 40 °C. The rate of heat-related deaths was much greater in black than in white people, and in persons bedridden or otherwise confined to poorly ventilated inner city apartment blocks. In the correspondingly severe five-day heat wave in England and Wales in July August 1995, a 10% excess of deaths occurred in all age groups, particularly in adults, from respiratory and cerebrovascular disease. In Greater London, where daytime temperatures were higher (and where there was less cooling at night), mortality increased by around 15% (Rooney

et al., 1998). The excess mortality was generally greater in socio-economically deprived groups, who typically lack access to air-conditioning of any kind. (The corollary of this heat-wave-induced rise in mortality was a lessened winter seasonal peak of mortality in an above-average warm year.)

There is a need for studies of the health impacts of extremes of heat and cold in Third World urban populations. It is important, especially in anticipation of global climate change, that urban planning and development should seek to minimize the adverse impacts.

Urban Ecological Footprints

Urbanism can affect human health directly, as a function of the properties of the urban physical and social environment. It also has an influence on a much larger spatial-temporal scale, via its distant impact on the integrity and productivity of the huge environmental penumbra that is the source of materials and services for urban populations. These are the *ecological footprints* of the city (*see* Ecological Footprint, Volume 3).

There are undoubted ecological benefits of city living. Cities confer various economies of scale, of proximity, and of shared use of resources. There are great but largely unrealized possibilities for reuse and recycling. Equally, there are great externalities. Urban populations do not subsist on their own urban land; they depend on food grown elsewhere, on raw materials (timber, metals, fossil fuels, etc.) extracted from elsewhere, and on having their wastes disposed of elsewhere. Thus, an urban population imports raw materials (thereby causing environmental damage at the source and in transit), makes demands on ecological systems on land and sea to produce food, dumps wastes into rivers, lakes and oceans, buries wastes on land, and emits wastes as gases and particulates into the atmosphere.

Urban populations thus depend on the natural resources of ecosystems that, in aggregate, are vastly larger in area than the city itself. The highly urbanized Netherlands draws in resources from a total surface area 15 times larger than itself. A study of the renewable resource appropriations by the cities of the Baltic Sea region showed that the amounts of resources consumed by 29 cities (wood, paper, fibers and food (including seafood)) depend upon a total area 200 times greater than the combined area of those cities (Folke *et al.*, 1996). That figure of 200 comprises 17 units of forest, 50 units of arable land and 133 units of marine ecosystems.

The scale of impact of urban populations is growing, and now includes massive urban contributions to the world s problems of greenhouse gas accumulation, stratospheric ozone depletion, land degradation, coastal zone destruction, and aquifer emptying, Via this scaled-up externalized impact, urbanism is thus jeopardizing the health of current and future generations.

DIFFERENCES IN POPULATION VULNERABILITY TO CLIMATE CHANGE AND OTHER GLOBAL CHANGES

The health impacts from global environmental change will vary around the world. Not only will the resultant environmental stresses vary in type and intensity in different geographic regions, but, in general, poor populations will be the most vulnerable; whether at the regional, national or subnational levels. With respect to climate change, the impacts of heat waves, other extreme weather events (e.g., tropical cyclones and droughts) and gradual coastal inundation would affect such populations most. Much of the anticipated increase in contagious and vector-borne infectious disease would occur in developing countries (McMichael *et al.*, 1998).

In many African, Asian and Latin American countries, the average life expectancy is 20 30 years less than for rich Western countries. Infectious diseases remain the main killer, particularly in children below the age of five. Much of this health deficit in poor Third World countries reflects the widespread poverty, the adverse social consequences of export oriented economic development, and the environmental adversity caused by exploitation of natural resources. In today s increasingly globalized economy, which operates to the general disadvantage of poor countries, the exacerbation of land degradation, rural unemployment, food shortages and urban crowding all contribute to health deficits for the rural dispossessed, the underfed and the slum dweller.

The plight of Sub-Saharan Africa, with its entrenched poverty and marginalization from the global economy, illustrates well these complex relationships. The region includes 33 of the world s 50 poorest countries, and trends in health, education, and living standards have reversed in the past two decades and are continuing to fall. Meanwhile, the region s population growth rates are the highest in the world, land degradation is increasing, and tropical forest clearance continues (World Resources Institute, 1998). A majority of Sub-Saharan Africans live in absolute poverty (Logie and Benatar, 1997). More than half still lack safe water and 70% lack proper sanitation. Infant mortality rates are 55% higher than in the world s other low income developing countries; average life expectancy, at 51 years, is 11 years less. Malaria and tuberculosis are widespread and increasing, while in parts of central, Southern and Eastern Africa one in three pregnant women are HIV positive. There can be no doubt that the two-way relationship between poverty and ill health erodes African economic productivity substantially, and also renders African populations very vulnerable to the adverse impacts of superimposed environmental changes.

There are various social, cultural and political influences on population vulnerability to environmental change. For example, Woodward and colleagues (Woodward *et al.*,

1998) have described poverty, environmentally destructive growth, political rigidity, dependency and isolation as causes of increased vulnerability. Their reasoning is as follows:

1. Impoverished populations are at greater risk because they have fewer choices, less information, and inadequate physical and social infrastructure.
2. Rapid increases in population size, density of settlement and the use of natural resources may increase vulnerability by damaging those ecosystems that buffer against environmental adversity. The devastation caused by Hurricane Mitch in November 1998 was, reportedly, greatly ampli ed by deforestation of large hillsides in the Honduras.
3. Political rigidity may have contributed to recent, greater than expected, impacts of climate-related disasters in parts of Asia.
4. In a globalizing world in which increased mobility of people and goods is connecting geographically remote countries to the international economic system, unconnected remoteness of a country may become a liability.

Changes in the age structure of populations will also affect vulnerability. As average life expectancies increase, so the proportion of elderly persons increases. Further, in developed countries increased longevity generally means an increase in the number of years lived with disabilities. In many developed countries, elderly populations have increased disproportionately in coastal areas and it is these areas that are, in general, more vulnerable to extreme weather events.

The impact of regional changes in food and water availability will be of particular public health importance in potentially vulnerable regions where population growth is pronounced and food insecurity already exists. Interactions between local environmental degradation and larger-scale environmental changes are likely to be important in determining the net impacts on human health and society. For example, local deforestation due to population pressure may directly alter the distribution of vector-borne diseases, and contribute to local increases (*see* **Demographic Change: the Aging Population**, Volume 3) in temperature (on top of any global increase).

In many populations, environmental insecurity is not simply borne of land exhaustion or the exceedance of local carrying capacity. Many traditional communities are under pressure because of the encroachment of increasingly globalized commercial activity. For the moment, con ict may not be evident because of the unequal power relations, but there certainly are widespread tensions. This encompasses, forest tribes in the Amazon (confronted by deforestation, displaced landless peasants, and the biotoxic methods of uncontrolled river bed gold mining), Ladakhi farmers whose traditional sustainable methods of farming are being undercut by the trucking in of government subsidized produce from large-scale intensive farming in India, and traditional rural communities in Zimbabwe where adverse maternal and child health consequences have resulted from the imposition of insecure seasonal employment in large export oriented plantations. Today s increasingly globalized food trade may, at a larger scale, have various adverse effects on whole countries and regions.

Demographic Entrapment: Controversial but Potentially Serious

Because of the combination of poverty, environmental decline and hunger with population growth, some of the world s poorest populations may be becoming demographically entrapped (King, 1990). That is, the weight of their current or projected numbers currently exceeds, or soon will exceed, the carrying capacity of their environment, and, lacking trade and migratory safety valves, they face starvation, disease or fratricide. Rwanda, where population size rst exceeded certain estimates of carrying capacity (around 6 7 million) in the 1980s, may be an example. Demographic, economic and environmental indicators in Malawi look similarly precarious.

Last (1995), too, refers to the notion of demographic entrapment, and describes how the desperate efforts of such populations to provide themselves with food, water, and fuel-wood can degrade an already fragile ecosystem into a desert that may take centuries to recover. This, he says, is happening in parts of Sub-Saharan Africa, in alpine foothills in the Himalayas and the Andes, in crowded small nations such as Haiti and Honduras, and elsewhere in Central and South America. Nevertheless, a reassuring counter-example comes from the experience of the Machakos district in Kenya, where, since the 1930s, a six-fold increase in population has been accompanied by a substantial regeneration of previously seriously depleted local soils and forested areas: albeit helped by an abundance of local rains in that location.

The notion of demographic entrapment remains controversial, and it is of course very dif cult to study. Indeed, debate about the relationship between carrying capacity and demographic entrapment discomforts many demographers. These complex life-sized problems, af icting whole regions or populations, are not reducible to simpli ed linear analysis. We need to develop a more interdisciplinary type of scienti c assessment that enables us to integrate across disciplines and sectors.

HEALTH AS A SUSTAINABLE STATE

The expectation that global environmental change will have various impacts, mostly adverse, on human health raises the unfamiliar issue of the *sustainability* of population

health. We conventionally measure population health cross-sectionally, as an *achieved* entity. This type of measure reflects, in large part, society s recent consumption of natural capital : but it tells us nothing about the possibility of sustaining (or improving upon) those achieved levels in the future. This is analogous to our conventional assessment of society s economic performance, wherein we measure accrued wealth and achieved output rather than some index of sustainable productivity.

To argue, therefore, that environmental conditions must actually be getting better since life expectancies are increasing is to misconstrue this type of environmental hazard. Gains in life expectancy tend to happen in circumstances conducive to rapid population growth that is, when the immediate carrying capacity (supply) of the environment exceeds the number of dependent individuals (demand). These generalized gains in human life expectancy indicate that, currently and recently, the life-supporting capacity of the human-modulated environment has been increasing. But we must ask, at what cost, or at what future risk?

The considerable and widespread gains in health and longevity over the past century have depended primarily on reductions in early-life infectious disease mortality. Basic gains in food security and in sanitation, supplemented by advances in vaccination, antibiotic treatment and oral rehydration therapy, have changed the profile of infectious disease mortality. These technical and social improvements have been closely bound up with the processes of urbanization, industrialization and increasing material wealth. They, and the resultant gains in life expectancy, have therefore (seemingly paradoxically) proceeded in parallel with increasing levels of physical disruption and chemical contamination of our ambient environment.

For how long can we expect to maintain these parallel increasing trends in consumption, life expectancy and environmental impact? At what stage might depletion of the world s ecological and biophysical capital rebound against the health of human populations? As discussed above, many of Earth s vital life-supporting systems are today showing signs of unprecedented systemic stress.

Risks to health will tend to increase so long as human societies depend upon a linear, high-throughput, waste-generating metabolism that is at odds with the circular metabolism of the rest of nature (wherein every output becomes an input). The high consumption lifestyle of Western nations depends greatly on continued access to inexpensive inputs from non-Western nations, resulting in depletion of natural resources or the co-option of traditional agriculture into export crop production. Meanwhile, as developing countries pursue their own economic aspirations, there will be additional strains upon the biosphere: and, therefore, increasing risks to population health in countries everywhere.

After two centuries of hugely increasing fossil fuel combustion by today s rich countries, further rapid increases in energy use in East and Southeast Asia must be anticipated to contribute greatly to the accumulation of greenhouse gases (*see* National Responsibilities for Greenhouse Gas Emissions, Volume 3). Continual forest clearance brings exposure to new and potentially mobile infective organisms such as hemorrhagic fever viruses (e.g., various arenaviruses in Latin America, Ebola virus in Africa). The over-fishing of the ocean and the decline and collapse of some fisheries appears to preclude any further gains in *per capita* supplies of seafood. Continued pressure on agro-ecosystems in vulnerable regions, coupled with land degradation and population growth, will (in the absence of yield-enhancing genetic modifications of foods, and their politically enlightened application in regions of greatest need (Hazell, 1999; Seragedlin, 1999)) increase migratory pressures and their attendant public health risks.

CONCLUSION

In this new millennium we are beginning to understand that large-scale damage to global and regional natural systems endangers the long-term sustainability of population health. We must think about population health and its determinants within a more explicitly ecological, systems-based, framework.

The prevailing economic ethos is shaped by rapid technological change, consumerism, a discounting of distant and deferred environmental impacts, and a pervasive free-market philosophy. Currently, the policy-setting role of national governments is contracting, as trade and financial transactions become globalized and deregulated, as the balance of power between private and public sectors shifts, and as the resultant cost-cutting competitiveness between nations puts a squeeze on social expenditures. Hence, at a time when coordinated, strong and farsighted government is needed to constrain damage to the world s ecological infrastructure, and hence too human health, we are instead entrusting our futures to the myopia of the marketplace.

Today, we face an unfamiliar range of hazards to human health from the various emergent global environmental changes. We must integrate this prospect into our thinking, planning, and preventive policy-making: without allowing it to diminish the importance of dealing with existing public health problems. In fact, both existing and future environmental health problems share many of the same underlying causes, relating to poverty, inequality, and social economic values and practices. The existing insecurity and vulnerability of many Third World populations makes more important the need to slow the environmental change processes while also shoring up the protective and adaptive capacities of populations in tropical countries.

In the near future we can expect to see increased efforts towards achieving a *sustainability transition*: one that embraces the essential idea of sustaining the conditions for healthy human life. This transition would require a transformation of our social and economic structures, values and practices. This topic is taken up in some detail in Volume 5. For public health scientists, the challenge is to forecast the population health impacts of a future world with and without such social and environmental change. The challenge for policy-makers and for the public at large is to incorporate the goal and values of ecological sustainability, and the sustaining of population health, into social policy.

Environmental Changes Driven by Civil Conflict and War

IAN DOUGLAS

University of Manchester, Manchester, UK

When the human drivers of environmental changes are considered, the devastation caused by civil con ict and war seldom receives adequate attention. However, in many parts of the world legacies of past wars and the impacts of continuing current con icts deny access to agricultural land, poison aquatic food resources and destroy vegetation. The impacts of war upon the environment are not only localized to individual regions, but also have global effects. There is no more environmentally destructive human activity than warfare. Its purpose is to damage or destroy the natural and human environments. Scorched Earth is an expressive term for a particular military tactic, but it captures the essence of the consequences of much of modern warfare.

As the con icts in Kosovo and the Gulf demonstrated, human deaths and the destruction of military targets are not the only immediate consequences of war. Modern weapons rely on toxic chemicals for much of their explosive force and propulsion. They create environmental impacts through their own composition as well as their destructive power.

BOMBS AND LAND MINES

When a heavy bomb goes off, it creates temperatures of around 3000 °C that destroy the local flora and fauna and sterilize and damage the lower layers of soil much more effectively than forest fires. The targets destroyed by the bombs also contribute to the environmental devastation of war. The air raids on Pancevo and Sremicica in the suburbs of Belgrade destroyed a plastics factory and an ammonia production unit in petrochemical plants releasing toxins such as chlorine, ethylene dichloride and vinyl chloride monomer into the atmosphere. These chemicals not only have an immediate and life threatening effect on humans but also have a residual effect on the environment.

The Gulf War produced similar negative environmental impacts through the targeting of oil tankers and oil production facilities. According to the 1993 *Marine Pollution Bulletin*, 6 8 million barrels of crude oil were spilled from sunken vessels (including Iraqi tankers) and from oil transfer facilities such as the Kuwaiti Mina Al-Ahmadi Sea Island terminal and Iraqi Mina Al Bakr loading terminal between January 19 28, 1991. Reports suggest that approximately 30 000 marine birds perished as a result of this incident, and this figure excludes those that were trapped in oil pools in the desert. Furthermore, approximately 20% of mangroves were oiled, 50% of coral reefs affected, and hundreds of square kilometers of sea grass infected. The deliberate burning of Kuwaiti oil facilities released gaseous pollutants, smoke and particulates to the atmosphere (*see* Oil Fires: Kuwait, Volume 3).

War often results in huge movements of people out of conflict zones to areas thought to be safer. This exodus to safer areas places great strains on the resources and environment of those regions. Thus both the war zone and the refuge areas suffer environmental degradation.

Often people cannot return to their homelands because of the unexploded bombs (UXOs) and land mines left there. Land mines are cheap, devastating and increasingly popular in regional conflicts. The International Committee of the Red Cross estimates that they kill or maim between 1000 and 2000 people every month. One hundred and ten million land mines now lie in wait around the world with two million more added each year. Peacetime detonations of land mines cause most victims. The Save the Children Fund has repeatedly stated that children are especially vulnerable to anti-personnel mines. The injury or death of a parent directly affects their welfare; their small size and curiosity increase risk of injury; and childhood occupations such as herding expose them to greater danger. Such injury and loss of family members reduces families ability to manage the land, to protect the soil against erosion and maintain food production.

Between 10 and 20 million land mines prevent people in Angola from making progress with recovery and rebuilding

in many parts of the country. The United Nations (UN) estimates that these silent killers have created 700 000 amputees in Angola. For three decades mines were scattered in Angola s elds, villages, roads, and other unexpected places to intimidate, maim and kill innocent victims. Land mines have a devastating effect upon the environment by restricting the movement of people, deterring farming, disrupting economies, and killing and mutilating many innocent men, women, and children.

It could be argued that by preventing access to elds and forests, land mines stop people altering the soil, cutting down trees, extracting minerals, or dumping chemicals. However, by their very nature, land mines are a people-made pollutant that adversely alters the environment for future generations. For example, in Angola thousands of kilometers of riverbanks, and tens of thousands of hectares of farmland, pastures, and forest are now unusable. In addition, the migration of people from the mined areas to towns and cities has led to other tracts of country being stripped of wood and wild game while water supplies have been depleted and contaminated, leading to increases in reported cases of dysentery, malaria and cholera. All the pressures on the land as refugees try to survive may lead to severe soil degradation and land cover change from forest and woodland to bare or sparsely vegetated soil.

Land mines, inexpensive to produce or buy and easy to distribute, are extremely dif cult to detect and costly to remove. In some places, mines seem to multiply faster than people. Cambodia and the Lao Peoples Democratic Republic (Laos) demonstrate their lasting environmental impacts particularly well. As a 1994 UN report stated, Cambodia has more mines than children; two for every child . After the Paris peace agreements of October 1991, which followed two decades of con ict, Cambodia had to cope with 385 000 returnees from Thailand, 190 000 internally displaced persons and 40 000 people maimed by land mines. Security problems persisted, with more than 5 million land mines still in place. After 30 years of con ict Cambodia is among the most mine- and UXO-affected countries in the world. In 1998, seven years after the 1991 peace agreement, mines and UXOs caused more than 1200 accidents. Most of the mined areas are in the provinces along the Thai Cambodia border where much ghting occurred after 1979. The Eastern provinces are mostly affected by UXOs (though there are also some mined areas) as a result of the Vietnam War.

In 1998 there were estimated to be over 14 000 km^2 of land affected by mines with a further 5300 km^2 suspected to contain land mines. Land mines affect the rural communities living along the Thai Cambodian border in various ways. There is a shortage of land for settlement, for agriculture, it is dif cult to rehabilitate rural infrastructure (schools, road, irrigation systems), there are obstacles to safe travel and to forest gathering activities to earn an income and there is no security for children.

The bomb and land mine legacy of the Indochina wars persists in Laos. Without a formal declaration of war, Laos became one of the most heavily bombed countries of all time. Between 1964 and 1973, the US dropped on Laos the equivalent of one B 52 payload of ordnance every eight minutes for nine years. Nearly 30 years after the cessation of hostilities, the debris of this bombardment continues to deny land to, and in ict casualties on, the largely rural population of Laos.

The physical and social effects of war still play an important role in current problems of environment and resource management in the Nam Ngum watershed north of Vientiane, the capital of Laos. War damage was especially heavy on the Plain of Jars in Xieng Khouang province, but other areas also suffered destruction of forests and villages. Aerial bombardment destroyed agricultural lands and forestry continues to be affected by shrapnel fragments lodged in trees. The northeastern part of the watershed in particular is still affected by bomblets from cluster bombs that still lie unexploded in the soil. No inventory of damage has been made to date, but remaining live munitions continue to cause injury or death to local people working their elds. Large areas remain uncultivable.

The wartime disruptions led many people to move outside the Nam Ngum watershed area, either to lowland areas closer to Vientiane, or to revolutionary strongholds close to the border with Vietnam. This in turn led to further forest clearance for cultivation, but following the war it also prompted renewed environmental destruction within the watershed area, because the returnees rice elds had been destroyed, as had their buffalo and farm implements. Moreover live munitions in the soil made plowing dangerous. For many years after 1975, former sedentary farmers relied on shifting cultivation, often in those areas of forest not badly affected by the war. Now hillsides have been converted from forest to grassland by shifting cultivation operating too intensively and lack of attention to re escaping from cleared areas to adjacent trees and shrubs. The legacy of war is severe land degradation, forest depletion and insuf cient cultivable land for wet rice production.

CHEMICAL DEFOLIANTS IN VIETNAM

Between 1962 and 1971, Operation Ranch Hand sprayed about 72 Megalitres (Ml) (19 million gallons) of herbicide. Forty-one Ml of this total were Agent Orange. The spray fell mostly on the forests of South Vietnam, but some was used in Laos, and some killed crops to deprive Viet Cong and North Vietnamese troops of food. The military purpose for using herbicides on non-cropland was to remove the vegetation cover used by Viet Cong and North Vietnamese forces for concealment. Along roads, canals, railroads,

and other transportation arteries, Ranch Hand cleared a swath several hundred meters wide to make ambushes more difficult. In Laos, the herbicide removed the jungle canopy from the network of roads and trails used for infiltrating men and supplies, making them more vulnerable to attack from the air. Ranch Hand also cleared large areas of forest that hid sanctuaries and bases, thereby forcing the North Vietnamese and Viet Cong to move or risk discovery and attack. In all, Ranch Hand planes sprayed herbicide over about 25 000 km^2, not correcting for multiple coverage.

The herbicides Ranch Hand sprayed were common agricultural chemicals in wide use in the US and other countries at that time. The most common ingredients in the herbicide mixtures were 2,4 D and 2,4,5 T, phenoxy herbicides that act as growth regulators and cause destructive proliferation of tissues in plants when they are in a stage of active growth. Another plant growth regulator used was picloram. Cacodylic acid, an organic arsenic compound, killed crops by causing them to dry out.

Crop destruction struck at the very heart of a rural South Vietnamese farmer s existence, eliminating not only the food supply upon which he and his family depended, but also obliterating in one spray pass the product of many months of his family s labor. The herbicides main effect on trees was to kill their leaves, and there was usually little lasting damage in future growing seasons unless the trees had been sprayed three or more times. Only about 12% of the total area covered by Ranch Hand received triple coverage. Mangrove areas in South Vietnam were an exception, because mangroves were killed by just one dose of spray due to their high sensitivity to herbicides. About 36% of the mangrove forest area in South Vietnam was destroyed and will not return to its natural state for perhaps a century without extensive reseeding.

The herbicides are thought not to have had any lasting effects on nutrients in the soil, with the possible exception of potassium. The more conventional wartime bombing and shelling had a worse effect on inland forests than herbicides. Besides killing trees, shrapnel imbedded in wood made logging both costly, and hazardous. The removal of trees by displaced people in the period immediately following the war probably caused more biomass loss than the defoliants. The collective impact of all these war-driven events has been to deprive much of Vietnam of mature forests. In 2000, few of the forest trees in State Forests in Vietnam were much more than 25 years old.

ENVIRONMENTAL EFFECTS OF THE KOSOVO CONFLICT

The European Commission s preliminary findings on the war in Yugoslavia (The Regional Environmental Center for Central and Eastern Europe, 1999) show a comprehensive range of environmental impacts. Surface waters suffered largely as a result of leakage from damaged industrial plants or pollution from poorly planned refugee centers. Specific impacts include the release of polychlorinated biphenyls (PCBs) from damaged transformer stations; leakage of oil products into the Danube River from the Pancevo industrial center and the refinery at Novi Sad; escape of more than 100 tones of ammonia into the Danube and release of more than 1000 tones of ethylene dichloride spilled from the Pancevo petrochemical complex into the Danube.

Air pollution impacts are thought to have been short-term phenomena. They include radioactive pollution from depleted uranium weapons. Vinyl chloride monomers (VCMs) reached concentrations of 10 600 times more than permitted levels near the Pancevo petrochemical plant. Polluted clouds carried the products of combusted VCMs: phosgene, chlorine, chlorine oxides and nitrogen oxides, Products from incomplete hydrocarbon combustion were released as a result of strikes on oil refineries. Following the Pancevo incidents, a 15 km long cloud of smoke lasted for 10 days. Concentrations of soot, sulfur dioxide (SO_2) and chlorocarbons increased by 4 8 times the allowable limits. Nitrogen oxides were released from jet aircraft and through burning industrial installations. Unusually acid rain was measured in several places in Romania and Bulgaria, the timing of which and the prevailing wind trajectories tend to link the acid rain with attacks on Yugoslav industries.

Much of the air and water pollution will eventually settle into the surrounding soil. Bombing has created deep craters in the humus layer, which will take years to recuperate. A 240 kg bomb makes a 50 m^2 crater. Not only are the craters unusable, but so is some land around the craters. The destruction of the upper layers of the soil means the destruction of its flora and fauna and degradation of habitats. Five national parks were directly affected by the conflict. In Albania some protected areas had refugee camps built within them (Rrushkull, Divjaka) and refugees changed land cover and aquatic ecosystems in nearby areas by felling trees and polluting water sources.

CIVIL CONFLICT AND FOREST RESOURCES

Local civil conflicts and insurrections are often more insidious than international wars. In addition to claiming 60 000 lives, the lengthy ethnic conflict in Sri Lanka has devastated the rich biodiversity of this island nation. Heavy explosives have destroyed natural vegetation, trees and parks in wilderness and urban areas, agricultural land, domestic and wild animals and birds. Since 1990, the separatist Liberation Tigers of Tamil Eelam and the government troops have cut down more than 2.5 million palmyrah palm trees (*Borrasus abellifera*), a staple of the people s diet in the north and east of the country. Palmyrah trees act as wind breaks, protecting the villages from damage by the strong

winds affecting this part of the country. Absence of forest wardens during the conflict has meant that much illegal logging has occurred.

Lack of control of land and biotic resources management during conflicts leads to uncontrolled exploitation, often with the connivance of the warring factions. Whether it is the illegal cutting and export of logs, the smuggling of diamonds or the uncontrolled alluvial mining of gemstones, the result is resource exploitation without any thought of the future. No replanting of trees, no restoration of mined areas and no control of erosion and sedimentation occur.

NUCLEAR WINTER

Despite the real situations described above the scenario of the likely environmental consequences of a major nuclear war would be truly global (Pittock *et al.*, 1989; Harwell and Hutchinson, 1989). A nuclear explosion at or near the surface of the Earth causes an injection of dust into the atmosphere. The fires ignited by the explosion also cause soot to be injected into the atmosphere. Models of the long-term behavior of this dust and smoke, based on those used for the injection of soot and dust from volcanic eruptions, generally assume that the nuclear explosions will occur in the Northern Hemisphere. The reduction of light levels due to the layers of dust and smoke causes severe drops in temperature at the surface of the Earth, this is termed a *Nuclear Winter* (*see* Nuclear Winter, Volume 3).

Although 10 25% of the soot may be washed out of the atmosphere within two weeks, modeling and satellite imagery suggest that the remaining smoke can be transported halfway round the world within two weeks. For example, the Chinese wildfires in May 1987 reduced daytime temperatures over Alaska by 2 6 °C later that month. In the first 1 3 months, the modeling predicts that nuclear war-created dust and smoke reduce solar heating of the land surface, without sufficient compensating infrared heat transfer from the atmosphere. The models predict that a large July smoke injection would produce a 22 °C drop in temperature in mid-latitudes. In humid climates the temperature drops are more moderate at about 10 °C. Over mid-latitudes there would be a 75% decrease in rainfall. In winter, temperature drops of only a few degrees are predicted. However, because the land would be colder to start with, more intense frosts and freezing events would be likely. Light level reductions would range from 0%, at low latitudes, to a 90% reduction in areas of high smoke injection. Ocean surface temperatures could fall by between 2 6 °C. The smoke and oxides of nitrogen injected could produce a long-term ozone depletion of about 50% or more. As a result, the ultraviolet radiation could increase up to 200% of normal levels. These changes would cause immense disruptions of ecosystems and major problems from human health, food supplies and wellbeing.

CONCLUSION

War and civil conflict lead to environmental scarcity, to forced migrations of people, land cover degradation and loss of biodiversity. Increasingly they have impacts on ecosystem biogeochemistry and ultimately the chemical residues of weapons and the damage to chemical processing plants will feed through the life forms and sediments in wetlands, lakes and coastal seas. The extent of war and conflict-induced land cover transformation cannot easily be segregated from vegetation removal through other processes. However, these impacts, of immense significance to the people and ecosystems immediately affected, contribute to the global consequences of changing land surface characteristics.

While war and civil conflict indirectly affect global environmental change, climatic changes will themselves be drivers of future conflicts. Sea level rises for example will induce migrations into other areas (*see* Environmental Refugees, Volume 4). Repeated droughts since 1960 have already been a major factor in causing civil conflicts and wars in the Horn of Africa, as people move from dry environments into better-watered territory already exploited by others. These environmentally related conflicts are not simple responses to climatic variations or changes. They are reflections of political events, changes in food production and marketing systems, traditional tribal land occupation and use, as well as deteriorating natural conditions (Suliman, 1999). Such complications should not be permitted to obscure the global significance of the environmental impacts of war and civil conflict, nor allow the sources of the weapons that make the destruction so pervasive to be forgotten.

A

Acid Sulfate Soils

Nazeer Ahmad
The University of the West Indies, St. Augustine, Trinidad and Tobago

Acid sulfate soils are problem soils which are worldwide in distribution, and which develop in marine and coastal inorganic and organic sediments in which iron sul de (pyrite) has accumulated over time. The accumulated plant biomass is also rich in organic sulfur, which on oxidation, adds to the pool of acid forming sulfate. On draining and oxidation, the black-colored pyrite (FeS_2) is oxidized to straw-colored jarosite ($Fe_3(SO_4)_2(OH)_6$). This reacts with soil water forming sulfuric acid and iron oxide, mainly goethite (FeO.OH) and in some instances, haematite (Fe_2O_3). While these processes are taking place, the soil develops extreme acidity (<pH 3.5) due to the formation of sulfuric acid, and the layer in the pro le thus affected is termed a sulfuric horizon. In this condition the soils are known as actual acid sulfate soils.

Potential acid sulfate soils are those rich in pyrite as well as sulfur in the organic residues of saline or brackish swamp vegetation which have accumulated in the soil body but which remained anaerobic due to continuous water-logging in coastal, estuarine, deltaic and riverain locations. The soil layer in which these accumulations occur is known as a sul- dic horizon. The soils have the capacity to become highly acid once oxidation is allowed to occur. The term acid sulfate soils was rst used by Chenery (1954) to describe these soils; although their extreme properties were known before, the soils were called by other names.

SOIL GENESIS

The environmental conditions for the deposition of pyrite and sulfur-rich soil materials (sulfidic materials) are normally met in shallow, saline or brackish swamps and marshes and in estuarine and deltaic locations. Even under the most favorable natural conditions, the rate of accumulation of pyrite is slow, around $10\,kg\,m^{-3}$ of sediment per 100 years in mineral soils (Dent, 1986). In these locations, mangrove (*Rhizophora* spp.), *Avicennia* spp. and other salt tolerant aquatic plants grow. The vegetation has three main effects in the evolutionary process of these soils:

1. acts as wind and water break of the coastal water, thereby encouraging mineral sedimentation of suspended material;
2. provides a source of energy for bacteria, mainly *Thiobacillus ferrooxidans*, which reduce the sulfate to sulfide in the transported sediments and which lead to the precipitation of the sulfide as FeS_2 (pyrite). This precipitate accumulates in the soils and results in a progressive development of a bluish-gray to black color of the soil material. The contributory conditions are a high content of easily decomposable organic matter and abundant soluble sulfate;
3. accumulates sulfate and organic sulfur compounds in the organic residues.

In equilibrium conditions, when pressure is applied on the surface of these inundated soils, gases escape, and the characteristic odor of H_2S is discernible. This odor becomes more distinguishable when the actual soft soil material is smelt and it becomes stronger farther down in the soil profile. Because of this unpleasant odor, these soils have long been known as *cat clay soils* by Dutch soil scientists since they claimed the smell was reminiscent of the excrement of cats.

Under natural conditions, the land would be inundated and the soil material quite soft. Ideally, the soil consists of an intimate admixture of mineral and organic residues. Not uncommonly, there may be layers of well-preserved organic materials alternating with layers of more mineral soil. These organic layers indicate deposition periods when the floodwater was poor in suspended sediments so the bulk of the deposited material originated from the vegetative cover. The entire profile can be predominantly organic for the same reason.

The concept of *soil ripening* is important in the development of these soils from freshly deposited mud, and embraces the physical, chemical and biological processes by which this material is transferred to a dry land soil.

Physical ripening involves an irreversible loss of water and consequent hardening of the soil. Clay and organic-rich sediments deposited in water have a very open structure and consequently a very high water-filled pore space. In this condition, the soil structure is easily deformed and the material has little friction or cohesive strength.

During accretion in a tidal environment, water is lost as a result of consolidation, evaporation and drainage at low tide and by extraction of water by plant roots. Removal of water leads to the partial collapse of the initial very open microstructure, and this is the soil ripening process. The degree of soil ripening can be assessed in the field by squeezing the soil in the hand and observing its behavior. (Smits *et al.*, 1962; Pons and Zonneveld, 1965).

Totally unripe mud is fluid; in predominantly mineral sediments, the water content is more than 80% by weight. Practically unripe mud is very soft, sticks fast to any surface and can be squeezed through the fingers by gentle pressure the water content can be between 70 and 80%. Half-ripe mud is fairly soft and sticky, and can be squeezed through the fingers the water content can be between 65 and 75%. Nearly ripe material is fairly firm; it tends to stick to the hands and can be kneaded and may have moisture content of between 55 and 65%. Ripe material is firm, not particularly sticky and cannot be squeezed through the fingers. The ripening process can be hastened with reclamation and drainage.

In the natural state, the soil is unripe, bluish gray in color and may be essentially mineral, organic or a combination of both. The pH value of the mineral soil in the fresh state is only slightly acidic. This is influenced by the solution of H_2S in the soil environment, by a soil cation exchange capacity that is saturated with Fe^{2+}, which is usually plentiful in the mineral sediments, and by other cations present in sea water. In this state, they are known as *potential acid sulfate soils*. It is only on drainage and oxidation, when the pyrite gets oxidized and mineralization of the organic sulfur progresses, that the acidity develops and the soils can then be described as *actual acid sulfate soils*.

Not all coastal, deltaic and estuarine soils are potential or actual acid sulfate soils. The potential for a soil deposited in a marine environment to so develop is a function of the rate of deposition of inorganic sediments. If this is very rapid, if the level of coastal inundation is too deep to allow vegetation to grow, or if the neutralizing capacity of the sediments is considerable, clay soils result with little pyrite material, or if present, the acidity developed on oxidation is neutralized; such material has little or no capacity to acidify on drainage.

The coastal soils from two geographical areas, i.e., the northern coast of South America and the coast of West Africa are strongly contrasting in this regard. The ocean water on the northern coast of South America is rich in mineral sediments of Amazonian origin and provides an environment for rapid mineral sedimentation. Consequently, good clay soils (Entisols, Inceptisols, Vertisols and Intergrades) predominate. By comparison, the marine-influenced soils on the coast of West Africa were deposited in an environment poorer in mineral sediments and acid; consequently acid sulfate soils are dominant.

SOIL CLASSIFICATION

According to *Soil Taxonomy* (Soil Survey Staff, 1975) the potential acid sulfate soils are classified as Sulfihemists in the Histosols if they are dominantly organic, and Sulfaquents in the Entisols if the soils are mineral and have pyrite material within 50 cm of the soil surface. Actual acid sulfate soils are classified as Sulfohemists in the Histosols if they are dominantly organic or as Sulfaquepts in the Inceptisols if they are mineral soils.

OCCURRENCE

On a world scale, acid sulfate soils are not extensive. In recent coastal plains and inter-tidal swamps, there are an estimated 12 million ha, mostly in the tropics, in which the topsoil will become severely acid or has already done so as a result of land reclamation. There is probably a much greater area of potentially acid sulfate soil material covered by a shallow layer of non-acid peat or alluvium (Dent, 1986). Large areas occur in the Far East in Vietnam, Thailand, Malaysia, Burma, Indonesia and Philippines, in West Africa (Senegal, Gambia, and Guinea Bissau (Marius, 1982) and Sierra Leone) (Bloomfield and Coulter, 1973), the Caribbean and South America (Suriname, Guyana, and Orinoco Delta of Venezuela and Trinidad) (Ahmad and Wilson, 1992). They also occur in temperate climates, i.e., New Zealand (Metson *et al.*, 1977), Australia, Canada, and in eastern United States and in Europe Sweden (Wiklander *et al.*, 1950), Denmark (Larsen, 1978), Finland (Kivinen, 1950), Holland and England (Dent and Turner, 1981). Changes in sea levels over the past 7000 years are related to the distribution patterns of these soils. In the Chao Phraya Delta in Thailand, for example, older sulfidic sediments of the Bangkok Plain are now 1 2 m above sea level and represent an earlier phase of deposition. They are succeeded, seawards, by a belt, about 100 km wide, of more recent marine alluvium that is mostly not potentially acid. Similar effects are present in the Mekong Delta in Vietnam (Dent, 1986).

IDENTIFICATION OF ACID SULFATE AND POTENTIAL ACID SULFATE SOILS IN THE FIELD

Due to the problem of excessive acidity when drained, it is very important to identify the soils in their natural state so

that adequate precautions can be taken if their reclamation and use are to be attempted. Such associated morphological features as soil color, soil consistency, presence of admixed organic material, jarosite mottles, root encrustations and the disagreeable odor of H_2S are always present. Where there has been some oxidation and development of acidity, the water in channels is clear and sediment-free and devoid of any fish life; these water courses are usually free of aquatic weeds but may have colonies of molds, iron bacteria and ochre (Trafford *et al.*, 1973). The water can cause skin irritation due to the content of dissolved acid. However, for positive identification, the pH value of the soil should be measured in the field, then a sample should be taken and treated with hydrogen peroxide or incubated for three months and the pH measured again. The values should decrease from near neutrality in the field to less than 4 in the incubated sample or to less than 2.5 after peroxidation (Soil Survey Staff, 1975; Brinkman and Pons, 1973).

It is obvious that in agricultural use, if these levels of soil acidity are allowed to develop on reclamation, they would cause Al^{3+} toxicity and plant nutrient deficiencies which would be important soil management problems (Ahmad, 1961). In the Caribbean, the Mara, Godineau and Alta Gracia soils (Table 1) are potential acid suppurate soils with an overlay of non-sulfate soil material. The Godineau soil has a buried sulfate peat layer deeper than 95 cm. By comparison, in the San Carlos soil, sulfuric conditions develop from the surface on drying. Note the high soluble sulfate contents throughout the soil profiles, which are associated with the low pH values. The other soil properties show the soils to be typical marine clays with high chemical activity.

USE AND MANAGEMENT

In many parts of the world, these problem soils occur in centers of high population density, so there is great urge to utilize them. In the process, there are many examples in reclamation where the land was over-drained, causing too rapid oxidation of the sulfidic materials, both organic and inorganic, with development of extreme acidity and the project had to be abandoned. In West African countries, the damming of rivers which prevent tidal influences in the flood plains resulted in over-draining of the land, and a transformation of some of the soils from potential acid sulfate (sulfidic) to actual acid sulfate in nature. The same process occurred in the Delta of the Orinoco in Venezuela and elsewhere. This process is not easily reversible (Ahmad, 1991).

Successful reclamation depends greatly on a full understanding of the properties of the soil. The main features to assess are existing or potential acidity, soil lime requirement, soil salinity, soil texture, degree of ripeness, and availability of good quality water for leaching. If acid sulfate conditions exist from the soil surface for instance, it may be advisable to leave the area as a nature reserve rather than attempt reclamation. Those soils that have an overlay of pyrite-free material do offer a much better prospect for successful reclamation. The main principles in attempting to utilize them are that oxidation of the pyrite and organic sulfur material should be controlled by careful water management. The main drainage system should be able to maintain the water table in the reclamation area at a sufficient depth below the surface to permit the leaching of salts and enough soil ripening of the topsoil to support agricultural operations. The field drainage should facilitate leaching of salts and create an aerated rooting zone for dry-land crops and a topsoil firm enough to support farm animals and light machinery. However, at the same time, the sub-soil-rich sulfidic layers must be kept anaerobic.

Continuous rice cultivation, in which the land is kept inundated for most of the year and the water drained off temporarily prior to harvesting of the particular rice crop, is one of the most sustainable uses for these soils. In this case, all operations have to be manual or utilizing only hand-operated light machinery. This use is common in Thailand and Vietnam and other Far East countries. In a few West African countries, where the crop is grown in rain-fed conditions, the land is formed manually in ridges or narrow beds, in which the relatively non-pyritic surface soil is concentrated for the growth of the crop.

In the Far East, advantage is taken of concentrating the non-sulfidic surface layer in raised beds that are then used for the cultivation of crops including vegetables, pineapple, food crops and even perennial crops. Shallow, wide drains of about 2 3 m in width are dug and the material spread on the intervening beds. The width and depth of the drains and the height of the beds are dependent on the crop to be grown and by the depth in the soil at which the potential acid sulfate condition is serious. The drains, in addition to providing the material to build the raised beds, serve to control the level of the water table. The depth of water in the field drains is maintained by a gate, where the drain discharges into the main drain; by opening or closing this gate, the level of water in the drain is maintained; there is also a similar device at the intake end of the drain to allow fresh water to enter. Good water must be available to periodically replace the water in the drains, which can become very acid. With this layout and these precautions, the soils can be used sustainably for production of a wide range of crops.

The other approach to utilization of adjusting the soil pH by use of ground limestone is not practical. Experiments have been conducted in different parts of the world which showed that up to 100 tons ha^{-1} of ground limestone may

[a] m.e., milliequivalents; CEC, cation exchange capacity.

be needed to appreciably increase the soil pH and reduce the level of exchangeable Al^{3+}. This requirement would only cater for the current acidity and not for the reserve acidity represented by the pool of sulfur present in organic form, or the unoxidized pyrite. Therefore, these high dressings of ground limestone may well have to be continued for some time. Phosphate fertilization has always proved to be very bene cial in association with lime, probably counteracting, to some extent, the high exchangeable Al^{+++}. Other fertilizers may also be necessary to achieve good production and this should be determined by experimentation.

Successive ooding with dilute seawater and subsequent leaching with fresh water as a means of reclaiming acid sulfate soils was tried in Guyana for sugar cane cultivation (Evans and Cate, 1962) in Sierra Leone for rice cultivation (Hart *et al.*, 1963) and in Denmark (Larsen, 1978). The treatment resulted in some change of the cation and anion population of the soil and related increases in soil pH in Guyana, but its wide use has severe restrictions, such as the ability to control the water so that other non-problem soils are not ooded in the process, and the availability of adequate amounts of good water for leaching.

Fish and prawn culture has been successfully carried out in countries such as Vietnam and the Philippines on acid sulfate soils. Without specific treatment, the yields are generally poor; however, with treatment consisting of successive flooding and draining after excavation of a new pond until the pH of the flood water in the pond remains stable at 5 or higher, and then incorporating lime, phosphate and chicken manure to the soil material and finally flooding and stocking, yields can greatly increase (Brinkman and Singh, 1982).

OTHER PROBLEMS

Environmental Impact

Where acid sulfate soils are developed, dramatic changes in the chemical properties of the associated water take place and these are exported from the reclaimed area with the drainage waters. Acid floodwaters generated over large areas of acid sulfate soils may adversely affect crops cultivated on adjacent better soils (Brinkman, 1982). Also, drainage from acid sulfate soils may affect aquatic plants, shellfish, crustacea and fish in both tidal and inland waters. Ferric hydroxide is deposited on the sides of streams and drainage channels and can accumulate in such quantities as to partially block them (Trafford *et al.*, 1973). Also, reclamation of these natural wetlands would result in loss of wild-life habitat and recreational facilities.

Engineering Problems

The chemical properties of potential acid sulfate or actual acid sulfate soils are detrimental to regular construction materials such as cement and steel. Several approaches are possible to counteract these problems. Steel can be insulated with bituminous material or covered with a layer of concrete. Protection can also be achieved by mixing lime with the soil layer surrounding the metal or concrete. In the case of concrete structures, sulfate-resistant cement and acid-resistant masonry or hardwood can be used (Dent, 1986). Any urban and industrial development on acid sulfate soils faces the engineering problem of uneven subsidence of unripe soils and corrosion of structural materials if adequate precautions are not taken.

Afforestation: Environmental Impacts

Piers Maclaren
Piers Maclaren and Associates, Rangiora, New Zealand

Forests, even if they consist of monocultural plantations, have a number of desirable effects on the environment. There are also a few negative impacts, but (depending on the circumstances) these are usually outweighed by the bene ts. Compared to a vegetation cover of grass or annual crops, forests usually provide greater protection against soil degradation, including soil erosion. They minimize the output of greenhouse gases and, indeed, can absorb large quantities of carbon dioxide during their establishment phase. They maintain water quality and reduce ooding in the headwaters of river systems during small storms. They have greater biodiversity. Their major negative effect is to reduce the annual total water yield: river ow is less, at all times of the year, if the catchment is in tall forest as opposed to short vegetation.

For the purposes of this article, *afforestation* is defined as planting of new forests on lands, which historically, have not contained forests. Given that trees are generally considered to be a climax vegetation (where soils and climate allow), why did some areas have no trees in the historic past? Regeneration of trees may have been prevented by human activities leading to frequent burning, livestock grazing, cultivation, soil nutrient depletion or waterlogging of soil. These practices can be reversed by such means as firebreaks, fences, fertilizer application and drainage. Climatic influences such as frost, or rainfall, can also explain the absence of trees in certain regions, but this can be overcome by planting hardy species and by irrigation.

Afforestation falls into two broad types: land abandonment and the deliberate planting of trees, usually for commercial purposes. Abandonment (called *old eld succession* in the United States) is a slow and haphazard process, which relies on the presence of seed sources from nearby forest remnants. Local inhabitants may come to regard such forests as natural, and seek their protection with the same vigor as they defend virgin old-growth forests. In contrast, commercial plantations often do not have a natural appearance. In order to maximize profitability, there is usually only a single species in each stand, planted in straight lines, with suppression of competing species (weeds). (A *stand* is an area of forested land containing trees of uniform age and species (or species mix), grown on a uniform management regime. It should not be confused with a *forest*, which is a larger unit, consisting of many stands). The chosen timber species may not be native to the region or the country, and is selected because it is relatively cheap and simple to grow and yields large quantities of marketable timber in a short period of time. Commercial forestry plantations can have more in common with an agricultural crop than a natural forest.

Most environmentalists are enthusiastic about natural forests, and seek their protection and enhancement. The environmental benefits of such forests are widely and readily acknowledged. Commercial plantations, however, do not always enjoy similar public support. These forests are often seen as a travesty of the natural model, with the profit motive creating a land-use that is not in the interests of the environment or the local human inhabitants. Such views can be based on emotion and prejudice, rather than on demonstrable fact, but nevertheless are a real and powerful factor in contemporary forestry throughout the world, and need to be taken seriously by foresters.

EFFECT ON SOIL

Soil quality is a subjective term, to a certain extent, because the sustainable productive potential of a soil cannot be discussed without specifying the intended land use. It appears possible, for example, that conifer plantations, on ex-pasture sites can cause a slight decline in the pH of topsoil and a dramatic reduction in earthworm numbers. Soil acidity can be a problem if the any subsequent crop requires a high pH, and if liming is not an economic option. But some crops (including conifers) prefer slightly acid soils. Similarly, earthworm numbers are not an issue unless we wish to have the sort of ecosystem that requires earthworms.

It is not possible, therefore, to state categorically that afforestation (even with monocultural conifer plantations) will cause soil deterioration, without being more specific as to what is meant. Under the influence of vegetation, nutrients on the surface of clay or organic particles can be made more available to plants, or else locked up. Such changes may be quite temporary, and removal of the vegetation can reverse the process. All commentators would agree, however, that soil can be said to have deteriorated if key elements, including nitrogen, phosphorus, potassium and sulfur, are actually removed from the site. This can occur by leaching (i.e., movement into the groundwater, under the action of rain or irrigation), by volatilization (i.e., movement of mainly nitrogen and sulfur into the air), or by extraction in agricultural or forest products.

Forests generally conserve nutrients very well. This is evidenced by the purity of the streams that flow from them. The mycorrhizal network regulates the decomposition, mineralization and uptake of nutrients in the forest floor in a way that minimizes loss to the system. In the absence of fire, there is also little loss by volatilization. Massive

depletion of nutrients caused by erosion is also less likely than in other forms of land cover. It is possible that trees, being deep rooted, can translocate nutrients from considerable depths and return these to the surface by means of litter-fall. There is debate, however, over whether this actually occurs in practice.

With regard to the removal of nutrients in harvest produce, forestry generally has a lower impact than agriculture, especially if the harvest is limited to stem-wood. This is because wood consists predominantly of a carbohydrate (cellulose, hemicellulose and lignin) which is derived from rainwater and carbon dioxide (CO_2), with minimum contribution from soil minerals. Indeed, carbon (C), hydrogen and oxygen comprise more than 99.7% of the oven-dry weight of stem-wood. In contrast, agricultural products can be rich in elements such as nitrogen, calcium, phosphorus, and sulfur, and these need to be replaced with fertilizers (organic or mineral) to avoid mining the soil.

It is somewhat academic to discuss soil degradation in terms of the concentration of essential elements, and their availability to plants, when the threat in many situations is a massive loss of topsoil as a result of erosion. For example, cultivation of fragile soils can cause wind-blown erosion, and removal of forest cover can cause slipping of soils on steep slopes. Topsoil loss must be the ultimate form of soil degradation. Not only can erosion strip a soil down to the parent rock, the ensuing silting of rivers can cause huge problems downstream. Poor forestry practices, particularly those involving roads or harvesting, can cause considerable soil erosion but in most cases this is avoidable.

Some degree of soil erosion occurs naturally, but human activity in many parts of the world has accelerated this beyond the restorative capacity of the ecosystem and its human inhabitants. Afforestation is an effective preventative, and partial cure, for most erosion. Trees reduce wind speeds at ground level. They maintain the soil in a drier state. Most importantly, they bind the soil with their strong, interlocked roots.

EFFECT ON WATER

Myths relating to the interaction of trees and water are widespread. It is not true, for example, that (in some mysterious way) trees attract rain. The energy of the sun causes water to evaporate, mainly from the oceans, and fuels the winds, albeit modified by the Coriolis effect. The forces involved are many orders of magnitude greater than the small influence of trees. Nevertheless, the water evaporated or transpired by trees adds to the humidity of the atmosphere and is likely to enhance rainfall elsewhere.

Trees influence the water cycle in two major ways. Firstly, and most importantly, they prevent rainfall reaching and penetrating the ground. They do this by interception of water on the canopy, and subsequent evaporation. Trees intercept and evaporate more water than short vegetation, not necessarily because they have a greater leaf area, but because there is greater air turbulence (and therefore drying and re-wetting) at heights farther from the ground. The second major influence of trees is due to the fact that, compared to annual crops, they are deep rooted. They continue to transpire water through their leaves long after annual crops have wilted and closed their stomata. In both of these ways, trees tend to dry the soil and prevent water reaching the waterways.

Decreased water flow as a result of afforestation can be expected at all times of the year. It is *not* true that forests act like a sponge, soaking up water during wet periods and releasing it slowly during dry periods. Indeed, even sponges do not work that way. Macropores release their water, within minutes, under the influence of gravity. In micropores, capillary action is stronger than gravity and the water is removed only by evaporation from the surface or by the action of tree roots, using osmosis. In New Zealand, reductions of water yield of 25 50% have been demonstrated, with the higher end of the range being observed on drier sites.

A forest floor has a high infiltration rate. This means that water will penetrate the ground rather than flowing over the surface, as may occur in compacted soils of agricultural systems. Improved infiltration may lengthen the time it takes for rainfall to reach the streams. In this way, together with the rainfall interception that occurs on the forest canopy, forests can act as a buffer against flood peaks. The role of forests in flood prevention, however, is often greatly exaggerated. Large storms overwhelm the limited buffering effect of trees. Also, in larger river systems, the profile of flood peaks is hardly affected by any smoothing that takes place in subsidiary streams.

The lowering of water tables following afforestation has at least one desirable side effect. In many arid regions of the world, deforestation has allowed salt laden water to reach the surface. Salt deposits then occur as a result of evaporation from saturated solutions (*see* Salinization, Volume 2). For this reason, agriculture in large parts of Australia may soon be abandoned. Planting trees in upland areas will lower the water tables and eventually (after many years of flushing by rainfall) the soil may be restored to its former productivity.

Fresh water is vital, and increasingly scarce in many regions of the world. Sometimes, planning authorities afforest key catchment areas in order to reduce soil erosion and maintain water quality. This is admirable, but it usually has the unwanted (and often unanticipated) effect of also reducing annual water yield. Hobson s choice is between abundant, but polluted, supplies or a depleted, but clean, water source.

There is no doubt that forests are the preferred vegetation cover for water quality. Even if water is derived

from deep aquifers, rather than shallow groundwater, such supplies can eventually become polluted by human activity at ground level. Pathogens (viruses, bacteria, plasmodia, etc.) present in agricultural systems can sometimes be prevented from reaching waterways, but nitrogen contamination is an intractable problem. Intensive livestock farming, or arable farming with nitrogenous fertilizers, will result in leaching of this element. This is almost inevitable, because nitrate salts are extremely soluble and can quickly bypass or overwhelm any filter or barrier. Above certain levels, nitrates and nitrites are considered to be a health hazard in drinking water, and are expensive to remove. Phosphates are somewhat less soluble, but are another major cause of water pollution. The end result of nutrient enrichment of waterways is undesirable aquatic growth, such as algal blooms. Toxins are released from these blooms, and (when the algae decay) water is stripped of its oxygen, causing eutrophication.

Other than pathogens and chemicals derived from farming, a main source of water pollution is erosion resulting from deforestation. Sedimentation can block rivers and cause them to overflow their banks (which is the major reason why afforestation is an effective preventative against flooding in larger catchments!). Silt can flow out to sea and block harbors, destroy fisheries, and so forth. Debate over the composition of trace pollutants in streams can become somewhat academic if the water is a thick silty soup.

EFFECT ON AIR

Plants remove carbon from the air by the process of photosynthesis and retain this in the form of wood. Half the dry weight of wood is elemental carbon. Land that supports a forest cover will hold considerably more carbon than land that does not, even if the forest is managed for production and parts are being felled and replanted at any particular time. The high carbon density (tonnes carbon per hectare) of forests is their primary contribution to the mitigation of global warming.

Many people have no difficulty with the concept of deforestation as a cause of increased atmospheric CO_2. The conversion of a high carbon density landscape (such as tropical rainforest) to one of lower carbon density (such as pasture) results in a transfer of carbon from the earth s surface to the atmosphere. Indeed, it has been calculated that global deforestation between 1850 and 1990 resulted in cumulative emissions of 122 ± 40 Gt C, compared to a contribution of approximately 230 Gt C from fossil fuels. In other words, deforestation is responsible for perhaps one-third of the CO_2 emissions over the last 140 years.

Many commentators fail to note that *reforestation* is merely the inverse of *deforestation*. If it were possible to restore the vanished forests in their entirety, this would compensate for the emissions caused by earlier forest removal. Just as forest clearance puts carbon into the air; so the establishing of forests takes carbon out of the air. The distinction between natural steady state forests and rotation forests is one of perception rather than one of substance relevant to carbon sequestration. Averaged over time, or over a whole landscape, both types of forest have a high carbon density.

Wood products do not increase the carbon density of the earth s surface to an appreciable extent. There is not much carbon in wooden buildings compared to the amount of carbon in trees. And while there is tremendous scope for reforesting large areas of the earth s surface and thus taking carbon out of the air, there is very limited potential for increasing carbon storage in the form of wood products. Their main value lies in the fact that they are a substitute for non-wood materials that use considerable fossil fuel and that emit CO_2 as a chemical byproduct, during their manufacture. A tree is a natural, biological solar panel and fuel storage unit. Wood is a sustainable, fossil-fuel-free product of solar energy.

EFFECT ON WILDLIFE AND PEOPLE

Afforestation, especially in tropical regions, creates an ecosystem that is considerably less complex than natural forest. The diversity of plants and animals is markedly inferior. But is this comparison valid? Afforestation is the conversion of a non-forest to that of a forest, and nearly always, this is a positive step in the direction of increased biodiversity. Forests have a vertical dimension that agricultural systems do not, and (despite attempts to control weeds) so-called monocultures can be surprisingly diverse. Also, in providing an alternative timber source, plantations may take the pressure off indigenous forests and thus protect natural habitats.

Local inhabitants can benefit from forestry, because the intrinsic biological productivity of a forest can be higher than the degraded landscape that it replaced. It can provide employment, and essentials such as house timber and firewood. About half of the world s wood is used for firewood, and this important item should not be overlooked. People can starve either because of a shortage of food, or because their staple diet (potatoes, maize, rice, cassava) requires cooking before it is digestible.

Some plantations are owned by large corporations and offer little benefit to local inhabitants. Commercial softwoods may not make good quality, slow burning charcoal, and may not provide the wealth of medicines, fruits, game and other products of the natural forest. Indeed, guards may be placed to keep locals out of the plantation. Criticism of this situation is often misplaced. The fault may lie with the ownership patterns of the community rather than with the land-use *per se*. Conversion of natural forests can be prevented by legislation, as there is (in most countries)

abundant non-forested land that is available and suitable for plantations. There is normally no need to replace complex natural ecosystems (which will usually regenerate well even after intensive logging) with simpli ed pulpwood plantations.

SUMMARY

Afforestation is usually driven by commercial imperatives. Cost minimization and revenue maximization dictate the creation of forests that are conspicuously arti cial. The comparison with natural forests generates a degree of hostility towards commercial plantations. Analysis of the environmental effects of plantation forests, however, shows that most of the bene ts are present in both types of forest. The true contrast is between forest and non-forest, and it is clear that the world would bene t from increasing the area of forest cover, even if this increase takes the form of tree plantations that resemble an agricultural crop.

Political pressure to restrict commercial afforestation will not necessarily result in a greater area of complex indigenous forest. More likely it will result in a continuation of the environmental harm that deforestation and non-wood substitutes has caused, and increased pressure to exploit and clear indigenous remnants.

Almost every sentence in this article is controversial, and therefore requires deeper discussion and source references. For further information, see Maclaren (1996) and **Forest: the FAO De nition**, Volume 2.

Agricultural Intensification in Java

Joan Hardjono
Padjadjaran State University, Bandung, Indonesia

Recent environmental changes in Java pose threats to the sustainability of land use systems. Centuries ago, farmers developed irrigation networks and rice cultivation techniques that enabled a growing population to be supported without disrupting environmental equilibrium. Further intensification in rice cultivation occurred when high-yielding seeds were introduced in the 1970s. Despite overall production increases, loss of genetic diversity in seed and the continuous cropping of rice led to pest plagues. Meanwhile, Java s resource base is deteriorating as greater deforestation and the cultivation of vegetables and secondary food crops on steep slopes give rise to wide-spread soil erosion. Sedimentation on the lowlands in turn leads to extensive ooding in the wet season and water shortages in the dry season. Con icts of interest in the use of land and water resources occur increasingly, as the ever-growing need to produce food comes up against the wish to cultivate commercial crops like tobacco for domestic and export purposes.

The island of Java in the Indonesian archipelago illustrates how human activity has led to environmental changes that are now threatening the sustainability of the very land use systems on which survival is dependent (Table 1).

For many centuries environmental equilibrium was maintained in Java, despite constantly greater intensi cation in rice cultivation associated with the need to feed a growing population (Booth, 1988). Farmers long ago learned that careful control of water ow and drainage, in conjunction with the transplanting of seedlings and frequent weeding, would give them high yields. As time passed, they found that they could increase rice output without disrupting nature by terracing lower mountain slopes and developing gravitational irrigation systems to divert water from rivers and springs when rainfall was inadequate. Even when technically controlled irrigation networks were constructed in the nineteenth century, to ensure greater reliability in irrigation for the intensive cultivation of sugarcane in rotation with rice (Geertz, 1963), there were no adverse environmental consequences.

Table 1 Java: land use, 1994

	Million ha	Percentage of total area
Rice land[a]	3.3963	25.7
Forest land[b]	3.0128	22.8
Dry fields	3.0807	23.3
Residential land	1.7325	13.1

Wooded land[c]	0.3211	2.4
Fish-ponds	0.1523	1.2
Fallow agricultural land	0.0879	0.7
Grassland	0.0428	0.3
Other land[d]	0.7725	5.8
	13.2190	100.0

[a] Irrigated and rain-fed land used for rice cultivation.
[b] Land managed by the Department of Forestry.
[c] Land covered in timber-producing trees, bushes and bamboo outside the authority of the Department of Forestry.
[d] Includes land used for public facilities and industrial purposes as well as rivers, lakes and reservoirs.

Intensification was taken a step further when the high-yielding rice seeds of the Green Revolution (*see* Green Revolution, Volume 3) were introduced at the end of the 1960s. By 1985, the national output had risen to a point where Indonesia no longer needed to import rice to feed its population of some 164 million in that year. But the new technology had ecologically adverse effects. Farmers found that heavy applications of chemical fertilizers caused a hardening of certain soils, which made dry-season plowing more difficult. More importantly, loss of genetic diversity in seed and the continuous cropping of rice on the same land led to the emergence of pests, in particular the brown plant-hopper (wereng or *Nilaparvata lugens*), the spread of which was encouraged by the use of pesticides that destroyed its natural enemies (Fox, 1991). The development of new varieties of rice provided only temporary solutions to the plant-hopper problem until a ban was imposed in 1986 on the use of most pesticides on rice, though not on other crops (Table 2).

Today, land is still cultivated intensively but monoculture is less common since the adoption in the mid-1980s of a policy of crop diversification in response to the decline that had occurred in the output of important secondary food crops like soy beans and corn. Rice-farmers are now encouraged to plant at least one non-rice crop every year and some are returning to traditional rice varieties in the interests of pest control and sustained productivity. As a result greater quantities of rice have to be imported every year.

Intensive agriculture on lowland Java has not been limited to the growing of rice. In many areas there is a long tradition of intensively cultivated home gardens in which cooking spices and herbs are grown in the midst of taller plants like corn and banana, with perennials in the form of fruit and coconut trees overshadowing and protecting them. Fertilizer is rarely used in these gardens, and insecticides are not needed because the ecological variety in plant species discourages the proliferation of insect pests. Environmentally, the system functions well, because the inter-cropping of species of different heights prevents the erosion of topsoil by heavy rain. Even where vegetables like tomato, chili and eggplant are inter-cropped in open fields in a pattern that involves continuous use of the same land, the careful leveling of fields and control of water prevents soil loss.

With ever-greater population pressure, however, environmental crises have become increasingly frequent in Java in recent decades. Most have their origins in soil erosion, which is causing rapid deterioration in the island s resource base. The need for additional arable land and for more employment in farming has driven the agricultural frontier farther up mountain slopes, causing accelerated change in land use systems. In some places change has involved intensive horticulture and in others expansion of the area under secondary food crops.

Table 2 Java: area and production of rice, 1961–1997

	Harvested area (10^3 ha)[a]	Output (million tons)[b]
1961	3992	9.2
1962	4087	9.9
1963	3647	8.5
1964	3655	8.4

1997	5381	27.9

[a] Irrigated and rain-fed fields.
[b] Dry, unhusked rice.

The development that has occurred in high-altitude horticulture can be traced in part to earlier land-use policies. In the late nineteenth century large-scale expansion in plantation agriculture took place at altitudes above 1250 m and on lower land on Java s southern mountain slopes, where poor-quality calcareous soils make the cultivation of annuals economically unrewarding. At the same time horticulture, often in conjunction with dairying, was established on a small scale in upland areas close to major cities to meet urban demands for vegetables.

Since the 1960s local farmers have been moving onto former plantation land and, in imitation of older horticultural practices, have planted crops such as cabbage,

cauliflower, carrot and potato, which bring better returns than perennials like tea, rubber, coffee and cinchona. Cultivators have continued to move upwards, and today are clearing land above 1700 m for vegetable growing. Adopting the intensive cultivation methods of rice growers, they transplant vegetable seedlings, weed frequently and hand-water crops when rainfall is irregular. In addition to animal manure, they use large quantities of chemical fertilizers to maintain soil fertility and apply pesticides to control the insects that thrive when as many as four crops of vegetables are grown annually on the same land. Due to the need to ensure good drainage, land is not terraced despite the readily apparent loss of topsoil from fields, which are often dug out on slopes greater than 45° (Hardjono, 1991).

At the same time, expansion in food-crop cultivation is taking place in the uplands on soils not inherently fertile enough for horticulture. The area under permanent tree cover is declining as farmers clear steep slopes to plant crops like cassava on land that they often neglect when prices are low. Meanwhile, other people remove trees of all kinds for sale as timber or fuel. Reforestation efforts have proved relatively ineffective, because with socio-economic pressures increasing every year, the forestry agency permits cultivators to inter-crop vegetables with newly planted trees, a practice that tends to impede tree growth and to encourage further encroachment on forested land. The consequences can be seen in the runoff of soil and in the landslides and flash floods that occur frequently in the wet season. At the same time, reduced infiltration of water on denuded slopes is affecting the flow from springs used for domestic purposes and farming at lower altitudes. While the replacement of primary forest by perennials a century ago had few adverse effects on the environment, the change from perennials to annuals has led to high rates of erosion in Java s major watersheds.

The consequences of erosion are being increasingly felt at lower altitudes in the sedimentation of rivers, canals and harbors and in the reduced storage capacity of the island s reservoirs, some of which can no longer provide the quantities of water needed to irrigate rice fields or generate electricity in the dry season. Extensive flooding occurs in many lowland areas every year, making the cultivation of any kind of crop impossible, yet pumps are needed to lift water onto fields in the dry season when water levels drop in rivers. Urban residents experience the consequences when floods damage infrastructure like roads, bridges and train lines and inundate low-lying, formerly irrigated farmland that has been converted to human settlements and factory sites.

The changes in aquaculture since 1980 along the northern coast of Java illustrate the way in which a long-established system of land use can have unfavorable environmental impacts when intensified, yet can itself be threatened in terms of sustainability by human activity elsewhere. Traditional fish-farming in brackish water ponds called *tambak* involves a modification of the mangrove forest ecosystem that constitutes the natural habitat of shrimp and milkfish. The economic profitability of these commodities has led to both intensification and expansion in area. Fish-farmers now use modern technology in the form of water aerators, pumps and manufactured fish-feed to produce greater quantities of shrimp per unit of land while at the same time clearing more land to make ponds (*see* Aquaculture and Environment: Global View from the Tropics to High Latitudes, Volume 3; Aquaculture in Asia, Volume 3).

The widespread destruction of mangroves has, however, led to a significant decline in the larvae and fry that fish-farmers need to restock their ponds and has exposed the coast to the abrasive action of the Java Sea. At the same time, deterioration of the environment some distance inland has begun to undermine the viability of the production system. Sedimentation has reduced the capacity of the channels that carry water into ponds and drain them, while the silt that passes into ponds carries with it traces of highly toxic fertilizers and insecticides. Ponds are increasingly affected by flooding, especially in the wet season when drainage canals are unable to carry water away from agricultural land in the interior.

The environment in Java has changed profoundly over the centuries since human settlement began. Intensification can go no further and today the long-term sustainability of agriculture is open to question. Even to maintain the present levels of production, measures are required that will restrict certain forms of human activity and for that reason are not likely to be adopted. Conflicts of interests in the use of land and water resources occur increasingly, as the need to produce food comes up against the demand for commercial crops like sugar, tea and tobacco for domestic and export purposes.

Agricultural Intensification in Western Europe

Ian Bowler
University of Leicester, Leicester, UK

Western Europe is one of the world's most intensively farmed regions, measuring intensi cation as agricultural inputs or outputs per hectare of farmland. However, there is variation between farm types and farm sizes and consequently intensi cation varies between regions within western Europe. There is some recent evidence to suggest a reversal of intensi cation (i.e., extensi cation) of agriculture in some regions in an era of post-productivism.

Intensi cation has been led by the demand for food from urban consumers, the production and application of new farm technologies, the in uence of food processing and retailing corporations, and intervention by the state. A range of damaging consequences has been created by agricultural intensi cation, including excessive costs of state intervention, the production of food surpluses, and environmental impacts in terms of air and water pollution and natural habitat loss. Most recently social problems associated with food health and safety have emerged, with consumers increasingly demanding food whose origins can be traced and whose quality can be guaranteed.

Remedial action is now underway, including a reduction in state intervention, the introduction of sustainable farming practices, payment for the production of environmental goods and reductions in purchased inputs into farming. However, climate change in western Europe will require further adjustments to production patterns and farming practices, with varied and uncertain impacts on the development trajectories of farming regions.

INTRODUCTION

Western Europe has emerged as one of the world s most intensively farmed regions, measured by either the inputs to, or outputs from, the agricultural sector (Dent and McGregor, 1994). Farming inputs and outputs can be examined as a ratio of the capital or labor employed in agriculture, but this analysis follows the convention of measurement per hectare of farmland. The contribution of livestock to farm production is a second global characteristic of western European agriculture, although the role of livestock, as with the level of intensification, varies between particular farm types and locations (Table 1).

The inputs to contemporary agriculture in western Europe are mainly purchased from the non-farm sector rather than generated on the farm. They include inorganic fertilizers (nitrogen, phosphorous and potassium), agri-chemicals (herbicides, fungicides, pesticides), crop seeds, livestock (pigs, poultry, milk cattle, beef cattle, sheep), plant (crop preparation for marketing, on-farm food processing), machinery (tractors, field cultivation equipment, milking equipment), livestock feed, petroleum and labor. Livestock feed, in particular, is purchased outside Europe, so that the farm sector effectively adds additional hectares to the western European farm, thereby contributing to the ecological footprint of western European agriculture (*see* Ecological Footprint, Volume 3). Land, as an input, is mainly owner-occupied, but with a rented (i.e., tenant-farm) sector; the intensive nature of agriculture is reflected in the high value of farmland, which causes it to be a resource for both production and consumption (i.e., investment).

The outputs from agriculture form the raw materials for the food processing, distribution and retailing sectors, but can be measured in terms of either volume or value. The most intensive outputs per hectare of farmland by volume are produced by crop farming, for example, cereals and field vegetables. Measured by value, however, horticultural, housed pig/poultry, beef feedlot and dairy production units are amongst the most intensive producers of agricultural products (Table 2).

THE CAUSES OF INTENSIFICATION IN AGRICULTURE

Intensification in west European agriculture has increased over time and the causal processes can be simplified to five headings: demand for food, farming technology, non-farm sectors of the economy, economies of scale and state intervention.

1. *Demand for food*: the urban population of western Europe is both numerous and relatively wealthy, expressing its purchasing power through a demand for high quality, high protein, processed foods. Livestock plays an important role in meeting this demand in terms of meat products, milk products and eggs, while the farming systems required to produce such products, especially in the volumes demanded, are intensive rather than extensive in character.
2. *Farming technology*: industrial capital has produced ever more sophisticated technologies (e.g., farm machinery, farming practices, crop varieties, livestock breeds) for raising the productivity of resources employed in the farm sector. The impact can be seen especially in the substitution of technology for farm labor; the latter, historically, has been the most expensive factor of production. This capitalization of agriculture, through the adoption of new farm technology, continues to raise the productivity of the land, displaces labor into the urban-industrial economy, and permits the evolution of intensive agriculture. The current controversy over the

[b] Totals do not sum to 100% as only a selection of products is recorded.

introduction of genetically modified crops is but the most recent manifestation of the long-term technological evolution of an intensive, industrialized agriculture.

3. *Non-farm sectors of the economy*: the food processing and retailing sectors form an increasingly important part of the marketing chain between producers and consumers. Food processing companies and major retailers, by exercising a control over the prices received in the farm sector, have created such nancial pressure on farmers as to require them continually to seek cost-reducing and output-increasing farm technologies (i.e., a price-cost squeeze). This process of induced innovation has ensured the continued application of new technology in agriculture, although historically the result has been to drive down the real value of farm gate prices. In addition, forward contracts between farmers and food producers and retailers, which increasingly characterize the food supply system in western Europe, commonly specify the farm technologies to be employed in agricultural production.
4. *Economies of scale*: in the farm sector, increased output can create economies of scale, whereby the costs of production are spread over more units of output (i.e., tons of wheat or litres of milk). But economies of scale can also be obtained by increasing the concentration of land into ever-larger farm units and by simplifying and specializing farming systems. The forces of competitive capitalism ensure the elimination of the least economically successful farming units and, through the land market, the acquisition of their land by larger, more successful farm businesses. On specialization, by eliminating all but the most nancially important farm enterprises, economies can be obtained in terms of farming and management skills, investment in plant (e.g., milk cooling and storage equipment) and machinery (e.g., potato planters, fruit harvesters), marketing contracts and volume of production. Specialization can be observed, for example, in the wine producing regions of France, Italy and Spain, the intensive horticultural regions of the Netherlands, and the cereals producing regions of northern France and eastern England.
5. *State intervention*: the state has been deeply implicated in these evolutionary trends throughout western Europe, rst through national agricultural policies and subsequently, since the 1960s, through the development of the Common Agricultural Policy (CAP) of the EU (*see* **Common Agricultural Policy (CAP)**, Volume 3). The state has: (a) subsidized research and development in the production of new farm technologies (e.g., experimental farms and research laboratories); (b) funded education and extension services, whereby advice and information on farming technology is diffused through the farm population; (c) supported the prices received

at the farm gate, thereby maintaining farm profits and the capacity to invest in new technology; and (d) subsidized programmes of farm modernization that have raised the intensification of agriculture. Taken together, the state has maintained an economic environment which, by reducing the risks attached to farm investment and food production, has stimulated the specialization of farming systems, financially rewarded investment in larger farm businesses, including raising the asset value of farmland, and encouraged the intensification of agriculture. This has been particularly noticeable in state price support through intervention agencies: not only has the farm sector in western Europe been sheltered from world markets and guaranteed a certain price for its produce, but export subsidies have enabled surplus production to be dispersed onto world markets, albeit at the cost of destabilizing the agricultural exports of other countries, such as the USA, New Zealand, Brazil and Argentina.

THE GEOGRAPHY OF INTENSIFICATION IN AGRICULTURE

Some perspective is needed on these generalizations, for the intensification of agriculture in western Europe is neither uniform nor unidirectional. Firstly, as already noted, the degree of intensification varies by farm type and, since farm type varies by location throughout western Europe, the intensification of agriculture also varies over space (Bowler, 1985). Secondly, intensification varies with farm size: in general, smaller farms have higher inputs and outputs per hectare of their land compared with larger farms. Since farm size also varies significantly by country and region within western Europe, so intensification varies over space. In broad terms, the intensification of agriculture is greatest in the Netherlands and Belgium and decreases outwards towards the regions at the spatial margins of western Europe. There are outlying regions of agricultural intensification, for example, in the Po Valley of northern Italy, Brittany in northern France, southeast England and along Europe s Mediterranean littoral.

Intensification in agriculture, however, is no longer unidirectional. There are now signs in western Europe of a counter-movement towards extensification, but again, the process is spatially variable (Laurent and Bowler, 1997). At issue is the evolution of agriculture: since the early 1980s, farm development has progressed from a productivist to a post-productivist era, led by a revision of state intervention in the farm sector. Rather than an orientation towards maximizing food production, as in the four decades following the Second World War, new objectives for state intervention are being set for the farm sector. These include the staged reduction in state financial support for agriculture under the CAP; the introduction of more liberal trading policies under the World Trade Organization (WTO), so that west European farmers are more open to competition from food producers elsewhere in the world; the development of farming systems that are more sustainable in their use of resources (e.g., integrated farming systems (IFS) and organic agriculture); the production of environmental goods (e.g., particular biotopes and landscapes), in parallel with conventional farm products; and the diversification of incomes within agriculture, so that producing raw materials for the food sector is no longer the sole objective for increasing numbers of farm businesses. To date there is little evidence of a reversal in the process of concentration of agricultural holdings (i.e., increasing average farm size).

Increasing intensification remains the dominant trend, the regions exhibiting the greatest rates of intensification being located in Scotland, southern England and central France (Figure 1), in association with a large-farm structure or the development of cereal farming (Jansen and Hetsen, 1991). Converse tendencies are detectable in other regions of western Europe, for example, extensification (i.e., lower inputs and outputs per hectare of farmland) can be detected in central Greece, northern and southwestern regions of France, Wales, Northern Ireland, northern England and northern Germany.

THE CONSEQUENCES OF INTENSIFICATION IN AGRICULTURE

Three groups of consequences have flowed from the intensification of west European agriculture: economic, social and environmental. In the first group can be placed the excessive costs of state intervention and the surplus farm production that it has generated. In the EU, the costs of the CAP escalated through the 1970s and into the early 1980s, so that by 1984 agriculture was consuming nearly 66% of the EU s total budget of 27 000 million ECU (Bowler, 1985). Most of the funding was spent supporting the prices of a handful of products (i.e., milk, cereals and beef), produced mainly in the northern regions of the EU (Table 3). In effect, technological progress in agricultural intensification had been so successful as to outstrip the more modest increases in the domestic demand for food. Moreover, the costs and prices at which farm production had been secured were so high as to render the surplus production untradable at world market prices without further export subsidies. At the same time as undercutting market prices for traditional agricultural exporting countries, such as the USA, New Zealand, Brazil and Argentina, and protecting European markets against competitive imports, the EU also purchased increasing quantities of animal feed and vegetable oil from all parts of the world, including some from developing countries.

On social consequences, research on the allocation of state subsidies to agriculture during the 1980s found that

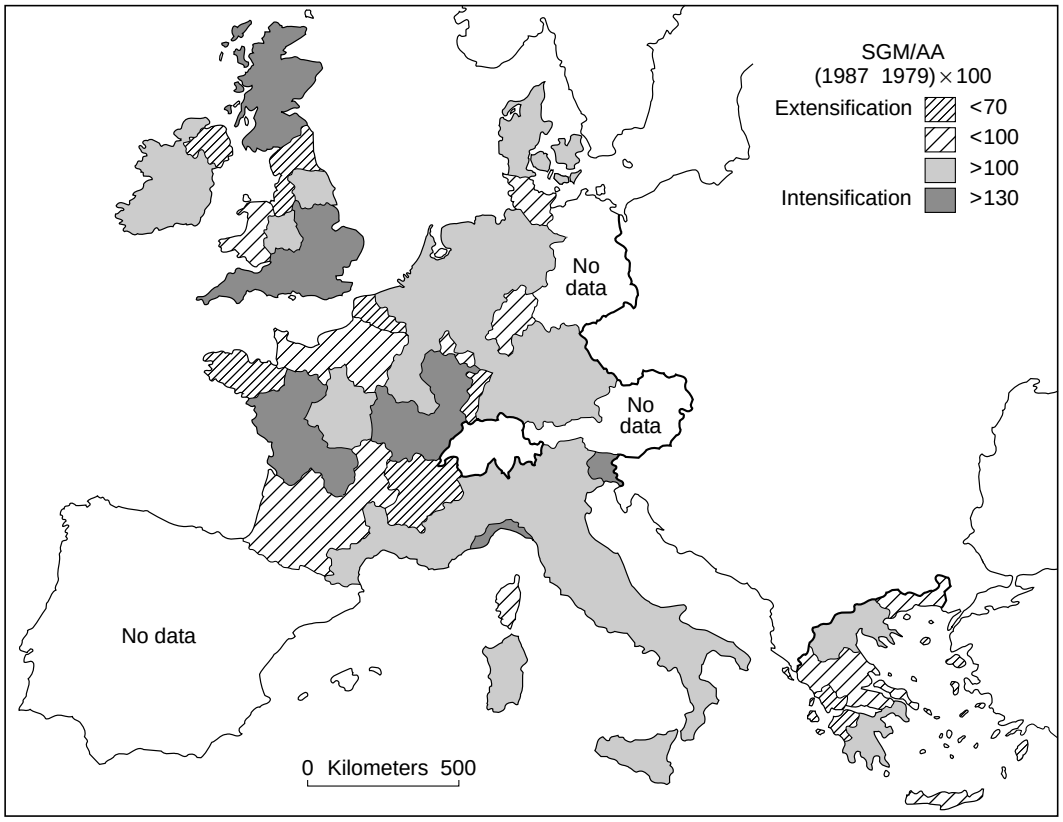

Figure 1 Changing intensification of agriculture within the EU, 1979–1987 (standard gross margin per hectare of agricultural land – SGM/AA). (*Source:* adapted from Laurent and Bowler, 1997)

Budget of CAP (% EU budget)	64	60	56
Guarantee element (% CAP budget)	93	92	90
Guidance element (% CAP budget)	7	8	10
Plant products (% CAP budget)	38	61	59
Animal products (% CAP budget)	52	27	24

[a] Official estimate. Compiled from data in the European Commission (various years) *Agricultural Situation in the European Union. Annual Report*. The Commission, Brussels.

the major beneficiaries were larger farms, located mainly in northern regions of the EU, rather than small, financially struggling family farms for whom they were intended. Moreover, a welfare transfer payment was taking place from poorer, tax-paying urban families to wealthier farm families, as well as between the regions and member states of the EU. A succession of food scares in the late 1980s and 1990s, notably the link established between bovine spongiform encephalopothy (BSE mad cow disease) and a new variant Creutzfeldt-Jacob disease (nvCJD) in humans, drew attention to the problems of health and safety for food produced by intensive farming methods. In sum, political, taxpayer and consumer support for intensive agriculture diminished in western Europe during the 1990s, as demonstrated by social resistance to the introduction of genetically modified foods at the end of that decade.

Arguably, pollution of atmospheric, water and soil resources, together with destruction of natural habitats, comprise the greatest impacts of agricultural intensification on global environmental change. On air pollution, intensive agriculture contributes to the emission of a number of greenhouse gases (GHG), with consequences for global and regional climate change. The conversion of grassland to intensive crop farming, for example, releases carbon stored in organic matter in the soil; the conversion of forests to crops and grass has released similar carbon fluxes over the last 300 years. Carbon dioxide is also released by the burning of crop residues, as well as the use of petroleum to power agricultural plant (e.g., grain dryers) and machinery (e.g., tractors). Nitrous oxide is emitted from inorganic fertilizers, while methane emissions are associated with enteric fermentation in beef cattle and milk cows and with stored

slurry (*see* Cattle Grazing: Impacts on Land Cover and Methane Emissions, Volume 3; Nitrate Protection Zones in Europe, Volume 3; Nitrogen: Agricultural Uses and their Impacts, Volume 3; Organic Farming and the Environment, Volume 3). An estimate for developed countries suggests that between 6 and 15% of their GHG emissions can be traced to agriculture.

Looking now at water pollution, this impact is related mainly to the increased application of inorganic fertilizers in both crop and grassland farming (Brouwer *et al.*, 1991). The nitrification of groundwater, and the eutrophication of watercourses, from the excessive spreading of fertilizers and animal manures from intensive livestock units, has been recorded across western Europe. In addition, evidence is mounting of the accumulation of pesticide residues in both soils and farm produce, and discharges of livestock slurry into streams and rivers (Kronert *et al.*, 1999). Such evidence can be added to other documented impacts of agricultural intensification, such as the compaction, erosion and salinization of soils and the lowering of water tables through the excessive pumping of water for irrigation.

Destruction of natural habitats, with increases in arable land, has also been reported from surveys across western Europe, together with the loss of diversified land uses (e.g., permanent pasture, rough grazings and woodland) (Kronert *et al.*, 1999). A broad reduction in biodiversity has been recorded both as regards flora and fauna. For example, the loss of biodiversity through the clearance of open olive and cork woodland has been recorded in southern Portugal and Spain; in the UK, a national survey of rough grazings (i.e., uncultivated marshland, moorland, hills and mountains), and their associated diversity of flora and fauna, recorded a decrease of 28% between 1945 and 1990.

ADDRESSING THE CONSEQUENCES OF INTENSIFICATION IN AGRICULTURE

Four broad approaches can be identified for addressing the damaging consequences of intensification in agriculture, namely: adjustment to farm prices, extensification of agriculture, sustainable farming, and agri-environmental measures. Looking first at agricultural prices, under the General Agreement on Tariffs and Trade (GATT, subsequently the WTO) the EU is liberalizing its markets for farm produce by the staged reduction in levels of price support, and the withdrawal of protection against food imports (Arden Clarke, 1992; Robinson and Ilbery, 1993). The anticipated, phased reduction by farmers of their purchased inputs (e.g., fertilizers and agri-chemicals), in the face of falling prices for their produce, is expected to produce significant environmental benefits. However, the relationship between reducing the level of state support for agriculture, and improved environmental conditions is indirect.

Turning now to extensification in agriculture, the EU is sheltering the farm population from rapid adjustments to farm prices by providing compensatory financial payments. For example, farmers who agree either to set aside their land from production (e.g., 10% of their arable area each year) or keep a limited number of livestock per hectare (beef cattle and sheep) receive direct payments (Ilbery, 1992). Another approach has been to compensate farmers in designated areas for reducing their fertilizer applications: this has taken the form of Nitrate Vulnerable Zones (NVZ) in the EU, where the designated NVZs are significant for the collection of water for human consumption (*see* Nitrate Protection Zones in Europe, Volume 3). One useful by-product of these land-use changes has been a modest reduction in GHG emissions from agriculture.

On *sustainable farming*, three dimensions are evident: integrated farming systems (IFS), organic farming and food quality (Ilbery *et al.*, 1997). IFS involves farmers in developing farming practices, such as the management of field margins to increase biodiversity, specified management practices to combat soil erosion (e.g., minimum cultivation, winter cover crops and contour ploughing), biological controls for crop pests and fungal diseases to replace agri-chemicals, green and animal manures to reduce inorganic fertilizers, and crop rotations for land use diversity. They aim to replace non-farm with farm-based inputs. Parallel state assistance for farm diversification aims to reverse the specialization of land use that is characteristic of industrialized agriculture, including the spatial separation of crop and livestock production. For instance, planting trees serves to diversify land use for a variety of objectives, including timber, shelter for livestock, commercial Christmas tree production, amenity and as an energy crop (e.g., willow).

Organic farming (i.e., farming without using inorganic fertilizers and agri-chemicals) is encouraged by financial compensation from the state for loss of income while the transition is made from conventional agriculture to certified organic production. The transition can take from two to four years, depending on regulations in particular countries, and during that time, crop and animal yields are reduced without benefit of the higher price premium that certified organic food attracts. Few countries provide subsidies to organic farming once it is established returns have to be gained through the market. To date, however, organic farming is supported by only a minority of consumers and, as a form of sustainable land use, it is in its infancy (*see* Organic Farming and the Environment, Volume 3).

Speciality food products (SFP e.g., farmhouse cheeses, hams, wines, berries, organic food, fruit and meat pies, meats, yogurts) are emerging as another means of addressing the damaging food health and safety aspects of agricultural intensification. Individual producers are supplying high-income, niche markets at premium

prices, thereby avoiding competition in mass-produced food markets dominated by large corporations. In effect, producers and consumers of SFP are acting together to create alternative food networks (Bowler, 1999). Quality assurance schemes have been developed through self-regulation by producer groups (e.g., cooperatives) and supermarket chains, while the EU has regulations 2092/91 and 2083/92 on biological agriculture (labeling and inspection), regulation 2081/92 on the protection of geographical indications and the protection of designations of origin, and regulation 2082/92 on certi cates of special character. Nevertheless, SFP account for less than 10% of the food market in the EU at their present level of development.

Agri-environmental measures include the direct regulation of pollution within individual countries and, within the member states of the EU, national Agri-Environmental Programs (AEP regulation 2078/92) (Robinson, 1991; Wynne, 1994). AEP represents a shift in the conservation effort away from individual sites (e.g., Nature Reserves, sites of special scienti c interest) towards more extensive tracts of countryside. Each member state has been able to develop and implement its own national schemes, with up to 50% of the cost paid by the European Agricultural Guidance and Guarantee Fund. The agricultural impact of agri-environmental schemes is spatially uneven, however, as reliance is placed on voluntarism and farmer response to nancial incentives.

CONCLUSION

A broad consensus of expert opinion believes that the contemporary level of intensi cation in west European agriculture is not sustainable in terms of economic, social and environmental development. Nevertheless, the level of intensi cation, and its associated problems, vary in magnitude and type between countries and regions. In particular, a broad polarization within western Europe can be detected. On the one hand lie regions favoured by climate, soil, topography or location near the main urban markets, where the continuing development of industrial agriculture and intensi cation can be observed. On the other hand lie regions lacking in those favorable attributes, with farming systems increasingly marginalized by changes in the agri-food system. Most of these regions lie around the periphery of the economic core of the EU. Ironically, the potential for the development of a more sustainable agriculture is greater in these latter regions with their orientation towards more extensive farming systems and practices.

Overarching these considerations, however, are the predicted climate changes associated with human-induced warming of the atmosphere ($+2\,^{\circ}C$ within a range 1.0 3.5 $^{\circ}C$) by 2100, with an associated rise in mean sea-levels ($+0.5$ m within a range 0.15 to 0.95 m) (Adger *et al.*, 1997). Regional estimates within global models (e.g., the Future Agricultural Resources Model of the US Department of Agriculture) predict a reduction in agricultural output within Europe, with wheat production falling by 11.6%, non-grain crops by 10.6% and the number of livestock by 1.5%. Within-Europe estimates are even more uncertain, but in broad terms climatic belts, and their associated crop and livestock production systems, are expected to move northwards within Europe, but at a scale and with consequences that cannot yet be predicted with any accuracy.

Agricultural Subsidies and Environmental Change

John Lingard
University of Newcastle upon Tyne, Newcastle upon Tyne, UK

With or without subsidies, agriculture as a major land use has a profound effect on the environment; environmental degradation by farmers has been going on for millennia, but many farmers have learnt to look after the natural resources that they use and have responded quickly to economic incentives to do so as they seek ways to sustain their livelihoods. Agricultural activities impact on the environment via soil quality (texture, erodibility, nutrient depletion, moisture balances, salinity and soil conservation, including ood protection and landscape), water systems, including surface and groundwater pollution and irrigation, air quality, including greenhouse gas emissions, biodiversity, wildlife habitats and ecosystems. Environmental change is an inevitable by-product of agricultural activity; policy instruments like subsidies may, by modifying both producer and consumer behavior, increase or decrease the rate of environmental change. Population pressures on the natural resource base are a further important source of environmental change, as an ever-expanding population attempts to satisfy its increasing demands for a wide variety of goods and services.

Conventional, neo-classical production economics theory suggests that input price subsidies/taxes and output price subsidies/taxes will promote intensi cation/extensi cation of production processes. Subsidies will increase the use of various kinds of production inputs, such as fertilizer, irrigation water, pesticides and herbicides; output price subsidies will change the optimal combination or factor proportions with which inputs are used, and they will lead farmers to substitute one crop for another or change between crop production and livestock production processes. Associated with this changing farmer/land user behavior will be different patterns of environmental impacts having both local and wider implications; that is, the environmental impacts will be felt at local, river catchment, regional and global levels. Examples include non-point pollution effects of agricultural activity, water quality and sedimentation, and the global effects due to the carbon balances of agriculture. There is some ambiguity about the role of subsidies and environmental change; subsidies by changing price signals may lead farmers to substitute polluting inputs for non-polluting ones, or to change from production processes which give low emissions (e.g., cereals and sheep) to those giving high emissions (e.g., dairy cows).

AGRICULTURAL SUBSIDIES

The environmental effects of economic support and subsidies to agriculture have recently attracted considerable scientific and political interest. Agricultural subsidies can take many forms, but a common feature is an economic transfer, often in direct cash form, from governments to farmers. These transfers may aim to reduce the costs of production in the form of an input subsidy, e.g., for inorganic fertilizers or pesticides, or to make up the difference between the actual market price for farm output and a higher *guaranteed price*. Subsidies shield sectors or products from international competition. The stated governmental aims of agricultural policy worldwide are many, but essentially involve farm income support and price stabilization. However, by artificially reducing the costs of production or providing taxpayers money for an output that nobody really wants (at least at such high prices), agricultural subsidies encourage wasteful use of materials, energy and natural resources and also encourage over-production.

Analysis of the environmental and economic impacts of agricultural subsidies is exceedingly complex, but many are unquestionably damaging, for example, the practice in forested tropical countries of providing cash incentives for clearing forest land for agriculture and livestock production. Similarly, subsidies to irrigation water, in the form of less than full-cost recovery pricing, encourage over-use of scarce water, and hence, water logging and soil salinization. In contrast, a subsidy to promote and encourage kerosene consumption may be environmentally beneficial if it reduces the demand for fuel wood and deforestation. Deciding which subsidies are, or are not, environmentally benign is extremely hazardous. Boldly stated, agricultural subsidies can encourage the production of environmentally harmful pollution, lead to the excessive use of natural resources and often impose high costs on consumers, taxpayers and government budgets. Their reduction/removal would increase economic efficiency, reduce government spending and, at the same time, improve environmental quality. Farm incomes and profitability will eventually recover following an initial adjustment period.

The exclusion of environmental externalities (e.g., pollution) from the profit and loss accounts of farmers and land users means that environmental damage caused by their economic activities is not paid for by those directly responsible for causing the externality. Private costs differ from *social costs*, and society and the environment must pick up the bill. This is often aggravated by government agricultural support or subsidy programs, which artificially raise the price of agricultural output and further encourage agricultural production and the associated, unpriced environmentally harmful by-products. Support removal, along with complementary policies to internalize social and environmental externalities, will lead to society *getting the prices right* and optimizing the economic system.

There is, however, no precise, easily disentangled, quantitative link between the size and type of agricultural support and the environmental damage caused. The linkages between support and the environment are complex and often indirect and depend upon:

1. agricultural input and output markets, competition within them, and particularly, the price elasticities or responses to price changes;
2. the availability of substitute technologies;
3. taxation regimes and institutional and regulatory frameworks;
4. the biophysical characteristics of the recipient environment, particularly its assimilative capacity. Farming practice effects on the environment will be dependent on site-specific, agri-environmental conditions.

This makes a general environmental assessment of the benefits of agricultural subsidy removal extremely difficult.

MEASURING AGRICULTURAL SUBSIDIES

There are a wide variety of government agricultural support policies and programs worldwide, and the measurement of subsidies is difficult. General Agreement on Tariffs and Trade (GATT) talks and World Trade Organization (WTO) discussions require quantification of agricultural protection by various countries in order to reduce complicated agricultural trade negotiations to measurable dimensions. A benchmark or baseline from which subsidies can be measured is required, and economists often use world prices as this benchmark; that is, the price that could be obtained if a product or resource was sold internationally. This is based upon the concept of opportunity cost to the nation. For example, if wheat sells for \$150 per tonne on the world market and the European Union (EU) pays its farmers \$200 per tonne, EU farmers are effectively being subsidized by \$50 per tonne. Likewise, if fuel oil sells for \$10 per barrel in a country but, if exported, could secure \$15 per barrel, then the domestic market is being subsidized by \$5 per barrel.

Producer subsidy equivalents (PSEs) are a widely accepted measure of the extent of agricultural subsidization (Cahill and Legg, 1989). PSEs measure the overall level of support to producers of a given commodity. Expressed as a percentage, they represent that part of the value of output accounted for by various kinds of market price support, direct income support, indirect income support and other support. If P_W is the unassisted price frequently determined by reference to the world market price, the price at which food imports are available at the border, then PSEs measure the gap between this price and the domestic price that the policy causes. For domestic price, P_D, output, Q, direct income support, D, levies, L, and combined indirect income support and other support, B, the PSE is defined as:

$$\text{Total PSE} = Q(P_D - P_W) + D - L + B \quad (1)$$

$$\text{Per Unit PSE} = \frac{\text{Total PSE}}{Q} \quad (2)$$

The total PSE is thus the net addition to the value of a commodity above the unassisted world price. The level of a country s PSE normally changes whenever the world price, in terms of that country s currency, changes: that is, it is sensitive to foreign exchange rate changes. In most developed countries, PSEs are positive, i.e., farmers are subsidized (and consumers are taxed); the higher the percentage PSE, the higher the per unit subsidy. However, in many developing countries and economies in transition, the opposite is the case and the PSEs are negative; i.e., farmers are taxed and consumers are subsidized a cheap food policy. A negative PSE is interpreted as taxation of farmers rather than subsidization or protection. Within the WTO talks, PSE measurement assumes a critical place. A reduction in PSE-type support is the objective; and reductions in PSEs are used to monitor the progress of trade reform. Table 1 presents some calculated PSEs showing the extent of agricultural subsidization across a variety of countries.

Few developed countries choose not to subsidize agriculture, although, not surprisingly, New Zealand and Australia, as countries relying to a large extent on agricultural exports, come closest to this. New Zealand completely dismantled its agricultural subsidies over the period 1984 1987; following the removal of subsidies, sheep numbers, fertilizer use and pesticide use declined and there was an increase in afforestation. Land prices initially fell by 60% and fertilizer use declined by 50%. However, they soon recovered, and by 1995, land prices were back to 80% of their 1982 values in real terms. Land clearing and overstocking, which had led to widespread soil erosion, were much reduced and the number of full-time farm workers actually increased. Livestock production, formerly encouraged by subsidies, which had

encroached on to erodible hillsides, is now being intensively practiced on better pasture land, and the hills are being replanted with trees. In 1995, agriculture and related industries accounted for 15% of New Zealand s gross domestic product (GDP) and agricultural products for 50% of New Zealand s exports. The EU and Japan still highly subsidize their farmers by paying them prices well above the comparable international trade prices; rice prices in Japan are some 8 10 times greater than world prices, and EU butter prices are much higher than those in New Zealand which largely determines the world price. The inflated price paid to Japanese rice farmers encourages them to safeguard their crops against any small risk of decreased yield. As a consequence, in 1993, the total rice insecticides market was $1.1 billion, of which 34% was spent in Japan, although Japan produces less than 3% of the world s rice. Subsidizing pesticide prices in Indonesia in the 1980s led to a large and unnecessary use of insecticides; when the subsidy was withdrawn and insecticide use was replaced by integrated pest management (IPM), rice yields continued to increase (Greenland, 1997). Inflated domestic prices can only be maintained by strict controls on international trade import tariffs and levies, quotas and non-tariff barriers; exports can only be sustained by facilitating export subsidies.

The calculated PSEs for other countries are less readily available, but for many African nations and central and eastern European economies in transition, they are probably negative. This means that farmers in these countries are, in effect, being taxed, not subsidized. Ivanova and Lingard (1994) calculated large negative percentage PSEs for a wide range of agricultural commodities in Bulgaria in the mid-1990s. This taxation results in low levels of profitability in Bulgarian agriculture, few incentives to use production inputs other than family labor, unsustainable soil nutrient management practices, obsolete non-functioning irrigation systems and a declining capital base for the production of vineyards, orchards and livestock breeding herds. A profitable agriculture would draw more resources to the sector, thereby ensuring that fewer resources are employed in less productive and more polluting industrial production. Within Africa, marginal land is often used for subsistence food production by squatting, poverty-stricken, landless laborers unable to find paid work. An increase in agricultural product prices to their comparable trade parity prices would increase employment on commercial farms and increase wages and incomes in rural areas. The taxation of agriculture is no real help to environmental improvement.

Agricultural support in the Organisation for Economic Co-operation and Development (OECD) member countries was estimated at $300 billion in 1996, some 1.3% of GDP, although this represented a decrease from 2.2% in 1986 1988 (OECD, 1998). Support to agricultural producers fell from 45% in 1986 1988 to 36% in 1996, as measured by the percentage PSE. The falls have, however, mainly arisen as a result of rapid GDP growth and high agricultural world prices rather than from deliberate policy reform on subsidy removal.

Policy reform driven by international trade pressures from the Uruguay round of the GATT, and subsequently by the WTO, is shifting agricultural support away from market price support and other support measures linked to farm input and output levels towards direct income support. Support which is decoupled from input and production levels does not have the built-in incentives to expand input use and production (and associated environmental externalities), but still aims to maintain farm incomes. Internationally, the policy instruments and levels of support vary widely by commodity and by country. However, market price support and support to inputs probably still account for over 60% of the total agricultural support worldwide. Agricultural subsidies thus stimulate high levels of input and natural resource use, wasteful production processes, and consequently, pollution. Reducing such subsidies is likely to reduce the costs of implementing environmental policy.

An *agri-environmental scheme* is a type of recent, new agricultural subsidy which is environmentally benign and helpful. These encourage land users to undertake agricultural practices with desired environmental results, rather than production enhancing outputs, such as public good provision (landscapes, flora and fauna habitats, biodiversity) or externality reduction. Support is coupled to the undertaking of particular environmentally beneficial farming practices to reward the farmer for the positive externalities that farming practices generate. Agri-environmental measures are being gradually introduced worldwide in developed countries in response to environmental pressures and political lobbying. Such schemes are, however, difficult to design, administer and monitor; frequently, they are merely a mechanism to compensate farmers for foregone market price subsidies. It is too early to determine what their long-term impacts on the environment will be and, in any case, their importance is dwarfed in comparison to market price support. For example, the UK spends approximately $300 million per annum on agri-environmental schemes, whilst the Common Agricultural Policy payments to UK farmers are in the order of $5 billion per annum.

Attempts to use subsidies to rectify market failures should follow the *polluter pays* principle, but rarely do. In terms of property rights, farmers are often assumed to have the right to pollute, and thus, have to be compensated for showing restraint. Likewise, governments have to compensate farmers for providing environmental goods in environmentally sensitive areas in the EU. This can be interpreted as the *polluter gets* rather than the *polluter pays*.

SUBSIDY REFORM AND THE ENVIRONMENT

Agricultural subsidies in rich countries are maintained by import barriers and export subsidies, whilst the agricultural policies of poorer countries tend to discourage farm production. The effects of these agricultural policies on the natural environment are poorly understood and under-researched despite numerous recent empirical trade liberalization studies. Based on the results from his commodity simulation model of world agricultural markets, Anderson (1992) argues that agricultural trade liberalization and the associated subsidy reductions could reduce global environmental damage from farming.

Liberalization would lead to falling agricultural prices in rich countries, resulting in less use being made of farm chemical inputs that pollute the air, soil and water. Chemical fertilizer applications and the use of farm pesticides are strongly correlated with producer price incentives. Lower use of irrigation water would reduce soil salinity problems; and reduced grain feeding of animals would reduce effluent disposal problems. Less intensive agricultural land use could result in more land being devoted to forestry, thus increasing the absorption of CO_2 from the earth s atmosphere.

Liberalization would, in turn, raise world agricultural prices and those in less developed countries (LDCs). This would make agricultural production in LDCs more profitable, increase the demand for farm labor and increase rural wages. Marginal workers could be attracted into the commercial sector, leaving behind subsistence practices on hillsides and resulting in less deforestation and soil degradation, particularly on sloping lands. The price of fuel wood might also rise due to increases in collecting costs causing the substitution of cleaner fuels, such as kerosene. Forests would thus be less depleted (80% of logs felled in LDCs are used as fuel). Higher royalty charges on logging and stronger enforcement of forestry property rights would help too. Optimal environmental policy instruments should be used in conjunction with the removal of distortions to agricultural output and input prices.

The WTO-related expansion of rice cultivation in non-Asian countries could lead to environmental problems in terms of water resources. Intensive cultivation of rice for exports would require expansion in irrigation and drainage infrastructures in Latin America and Africa. In designing such systems, particular attention will need to be given to the problems of water-induced paddy land degradation which have occurred in Asia, such as salinization, soil toxicity build-up and water logging.

Caution should, however, be exercised with respect to these conclusions. They are based on weak links between agricultural prices, production levels, input use, production technologies and environments. Differential population pressures at local, regional and national levels can substantially change, modify and even invalidate the findings. Further research is required.

CONCLUSIONS

Subsidy reform is now a central plank of the environmental policy and international trade agenda. International cooperation in reducing agricultural subsidies will facilitate support removal/reduction and reduce the negative side-effects that may accrue to any one country. Negotiating multilateral reduction of agricultural support which is common in many countries could lead to increased environmental benefits and reduced government expenditures, with little loss of competitive advantage in the agricultural sector of any one country. It is unclear whether the continued subsidy reduction and opening up of markets presents opportunities or threats to farmers in economically marginal, but ecologically valuable land, and what the impact on natural resource management might be. However, a simple message still remains:

> if you want to start saving the environment, stop financing its destruction by agricultural subsidization.

Agroforestry

Annette Hladik

Eco-Anthropologie, CNRS and Muséum National d'Histoire Naturelle, Brunoy, France

The agroforestry approach combines the study of woody perennials, herbaceous plants, livestock and people, and their interactions with one another in farming and forest systems. It embraces an ecosystem focus considering the sustainability and equitability of land-use systems, in addition to their productivity; consideration of social as well as ecological and economic aspects is implied (Leakey and Newton, 1994).

Agroforestry is the name applied to a large diversity of traditional resource-use techniques and cultural patterns concerned with the management of trees since time immemorial mainly by people living within tropical countries. Agroforestry systems are dynamically linked to the long-term survival of the societies that practice them. Such agroforestry systems might be centered upon forests whose composition is deliberately manipulated. Alternatively they may comprise agricultural systems based on crop production of either annual or pluriannual cultivated plants, mixed in various patterns and cycles on the same land area, together with trees for multipurpose uses (shade, fruit crops, leaf fodder, timber, latex, resin or medicinal products . . . ;) and domestic animals. Around villages, and in small towns of many tropical countries, there exists an ecologically complex landscape made up of species-rich natural forests, and agroforests or community managed forests, alongside pasture lands, intensively cultivated permanent fields, and extensive rotational fields with fallows in different stages of succession. Within this mix of approaches, agroforestry systems show high biological resilience; they control soil erosion, promote nutrient cycling and maintain organic matter. This is a potentially flexible and reproductively viable long-term land-use mosaic provided that the biodiversity is maintained and even increased. It is socially and politically promising for the future development of sustainable agroecosystems.

Agroforestry is an emerging science dating from the 1970s, based on concepts adopted from various tropical regions where flexible land-use mosaics predominate. It links scientists from agronomy and forestry, two fields with research agendas that have always been conducted separately in the developed countries. Agroforestry grew out of new understandings coming from researchers working in tropical forest ecology and anthropology. They stressed the importance of analyzing the dynamic processes that underlie the functioning of forest ecosystems, based on the complex interrelationships between their numerous living species (mutualism instead of competition). They also considered the optimal production of such systems rather than just their maximal production, and paid attention to random events from many sources: climatic, biotic, economic, cultural, and familial.

MANAGED FORESTS AND COMPLEX AGROFORESTRY SYSTEMS

It is generally recognized today that there is no such thing as an untouched primeval forest. People have been present in all forests for many thousands of years. Forest biodiversity has coevolved with humans as well as with other biological species. Everywhere, the forest space has been managed; even before indigenous people practiced agriculture, they

gathered forest products from plants that were tended and protected; and they still do so.

At present, three million indigenous people live in the tropical forests of the central African zone (including about 120 000 Pygmies) and 8.45 million live in the Asian tropics (including about 180 000 hunter-gatherers). In Amazonia, where many more indigenous people lived in the past, today only about 700 000 Caboclos and Amerindians occupy this vast area (estimates are from Bahuchet, 1993). Population densities affect the way forests are managed. In the Brazilian Amazon, where the concept known as *extractivism* prevailed, the procurement of renewable resources used for sale was possible on a more or less sustainable basis because large areas of forests existed, allowing for the creation of extractivist reserves. Yet even here, renewable resources may be seriously over-used and extractivist techniques may threaten biological diversity. Cultivating the forest is the only promising alternative. This is precisely what happened in Java and Sumatra, which have had high population densities (per unit area) for a long time. Here, traditional communities have created complex agroforestry systems based on numerous cultivated tree species planted close to their irrigated paddy fields and dry rice fields in swiddens opened up in forests (*see* Agricultural Intensi cation in Java, Volume 3). Farmers, most often women, need species-rich forests where they could gather a multitude of essential products.

The term *community forest* is generally used by official organizations (for example, within the Food and Agriculture Organization (FAO)), to designate the traditional aspect of agroforestry systems that are managed by local people. But, the term community implies the idea of local ownership, whereas government officials insist that forests belong to the State. The interrelationships that exist between particular people and their forests are constantly being shaped and re-shaped by changing social and political circumstances. In countries where the state claims ownership, officials tolerate local people s use of their forest as usufruct (the right to use another person s property provided that the user does not damage or waste it). When farmers cultivate trees within agrosystems, they assert their ownership over the land. Generally, tree species are planted along the edges of fields, as a traditional way of delineating property boundaries. In some countries, in fact, efforts have been made to place the responsibility of delimiting community forests in the hands of the villagers themselves. This is not an easy process to decree by laws.

In recognizing that diversity (be it biological or cultural) constitutes a fundamental value and a key concept for insuring future sustainability, it is important that it be extended to include land use and land rights. There are various types of ownership even within such categories as private versus public land. There are also diverse forms of common ownership: land may be the property of an entire village, or only of certain descent groups, designated households or family groups. Moreover, within traditional communities, land rights might not be coterminous with rights over the products obtained from the land. Access to forest products is often subject to seasonal rules, even for the owner. In addition, some part of the forest may be set aside for special (ritual, social) use and thus be out of bounds for some community members.

Multi-purpose, traditional agroforests yield products not only for subsistence but also for commercial purposes. Households need additional income to fulfil obligations linked with the modern world (schooling, taxes, clothing and implements). But the problem with commercial production is the absence of infrastructures, mainly transportation facilities to take the products to the market. Moreover, market forces require the flexibility to be able to balance supply and demand particularly because profit margins may be low. The diversity of agroforestry outputs may be either augmented or reduced by consumer choices. Preferences for particular food products are subject to cultural preferences that are often highly arbitrary. There is an urgent need to create and develop new markets for new products. Clearly, the potential productivity and income-generating capacity of agroforestry systems are immense, but the constraints surrounding them are often insurmountable in developing countries.

AGROFORESTRY: TRADITIONAL KNOWLEDGE

The value of a holistic approach, including traditional knowledge about forest ecosystems, is now amply recognized. The term *tradition* does not necessarily imply past and obsolete; it may also suggest modern and promising ways of incorporating change in the modes of thought and behaviors followed by a people throughout the generations. In fact, continuity is a dynamic idea; it accommodates new adaptations and embraces new ways of doing things. As such, it is the opposite of a conservative view. The ability of traditional peoples to invent and to incorporate new methods, new tools, and new species into their resources practices leads to an incredible diversity of traditional resource-use patterns. The survival of small-scale, indigenous communities over generations in their forest habitats is evidence of their success. Indigenous knowledge about forests is thus an essential component of traditional ecological knowledge (TEK).

AGROFORESTRY RESEARCH

History and Literature

One of the first scientific papers clarifying the concept of agroforestry appeared in 1977 (Bene *et al.*, 1977) at

the International Development Research Center (IDRC), Canada. It is a summary of discussions, which took place among experts concerning the relationship and balance between sustainable forest management and agricultural food production. Shortly after, in 1978, the International Council for Research in Agroforestry (ICRAF) was created in Nairobi. At the same time, a new scientific journal appeared entitled *Agroforestry Systems*. Organized at different scales, either national, regional or international, several symposia took place in various countries, including the regional workshop convened in Makokou, Gabon, in the context of *Man and the Biosphere* (MAB)/United Nations Educational, Scientific and Cultural Organizations (UNESCO) on the potential contribution of agroforestry systems to conservation and use (Maldague *et al.*, 1986). Several newsletters are now available, among them *Forests, Trees and People Newsletter* (FTPP/FAO) and *Agroforestry Today* (ICRAF). Bibliographical records containing useful references to agroforestry approaches and practices have also been compiled. Moreover several important books on the subject of agroforestry have been recently published; they are listed at the end of this article.

Universities and research centers nowadays regularly offer programs in agroforestry concepts and management. The subject has become an essential component of an academic programs in the agricultural, sylvicultural and related sciences.

System Analysis

An extensive survey and analysis of traditional agroforestry diversity and functioning has confirmed that such systems are generally complex, reproducing the multi-structure organization of a natural forest (Figure 1). An analysis of this complexity indicates that it is not only created by the manipulation of the plants themselves but also by the modification of the environment where they grow through irrigation, exposure to light, composting and seed selection. One of the most threatening factors requiring careful management is natural pest control through the use of a diversity of plant species and varieties. An integrated approach to the *in situ* amelioration of plant genetic material and the conditions under which different varieties do best, creates a veritable gardened forest. Sometimes, agroforests are entirely reconstructed after a field has been harvested by planting selected species (producing rubber, damar resin, cinnamon, nutmeg, clover and durians) in association with spontaneously regenerating native species (De Foresta and Michon, 1993; see also Figure 2). The complementarity in space and time, and the production of numerous selected, as well as spontaneous, species are the primary advantages of these gardened forests.

In the last few years, foresters from the FAO have placed great importance on trees out of the forest. For FAO scientists there are only natural forests, plus forest plantations; they assume that swidden cultivation leads to deforestation. In fact, a field that has been cleared and cultivated for two or three years will revert to various stages of regenerated forest. One can recognize first regrowth, middle regrowth, young forest and so on, until a mature forest evolves. All these stages and more are specifically named in the local languages. Unfortunately, with increasing population pressure around villages, long forest fallows are often shortened and the forest has a reduced chance to recover enough of its diversity (*see* Shifting Cultivation and Land Degradation, Volume 3). Satellite imagery and geographical information systems (GIS) linking spatial geographical data to events occurring at ground level can be used to obtain an approximate determination of the extent to which an area has been deforested. These essential tools for any type of natural forest management, including conservation, are not without their problems. There may be selective logging and other destructive activities occurring under the forest canopy that cannot be detected by satellite imagery. This is why ground truth is an essential component of all GIS analysis.

Experimenting with New Agroforestry Systems

The new agroforestry research is based on an interdisciplinary approach integrating studies concerning soils, plants (mixed cultivated plant species: annual and perennial crop, herbs and ligneous plants, trees and vines or lianas) with that of animals (cattle and poultry). Research into how human societies manage these plant animal interactions requires not only technical knowledge but also economic and cultural information.

When it comes to testing associated mixed plant species, experimental agroforestry systems are highly simplified when compared with most traditional systems (Figure 3). For example, the alley cropping system promoted by various governmental agencies and non-government organizations (NGOs) involves one crop species (even one variety) plus one shade-tree species, planted in lines. Moreover, alley cropping and hedgerow intercropping do not eliminate the need for chemical fertilizer. Thus, in an effort to test and control for variables, technicians have greatly reduced the complexity of experimental systems and made them more dependent upon outside inputs. An especially problematic case is that of the Taunguya system where peasants are encouraged by foresters to plant trees in lines and grow their crops in the spaces between. This may be a good reforestation procedure but it is not adapted to peoples long-term use of the land. There is always a risk of uncertainty in the creation of artificial systems whose species composition and interactions have not been tested through time. By leaving out the human factor, one decreases the ability of individuals themselves to learn and cope with production constraints.

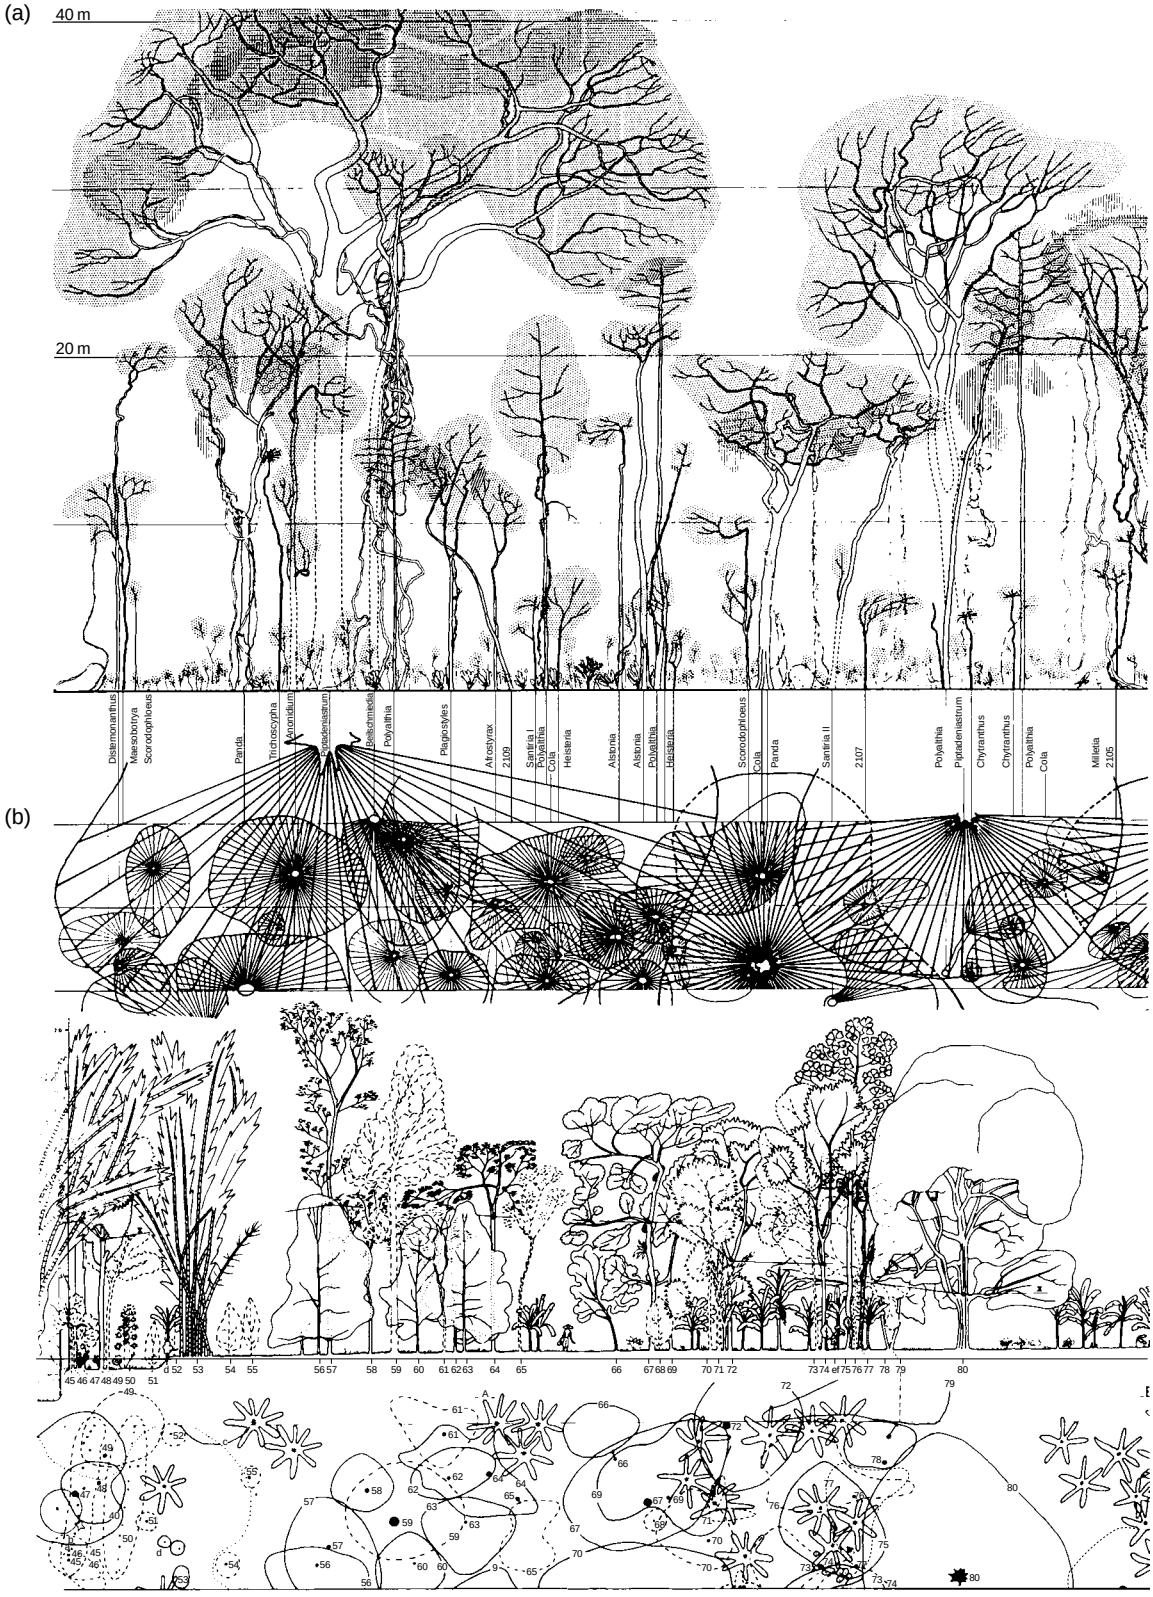

Figure 1 The multi-structure organization of a complex man-made agrosystem, as shown in (b), in Java where banana plants are mixed with forest trees (plot of 10 × 60 m) compared to a species-rich rain forest (as shown in (a)) in Africa (same plot 10 × 60 m with the profile only 5 m wide). (Reproduced from Hladik and Hladik, 1984)

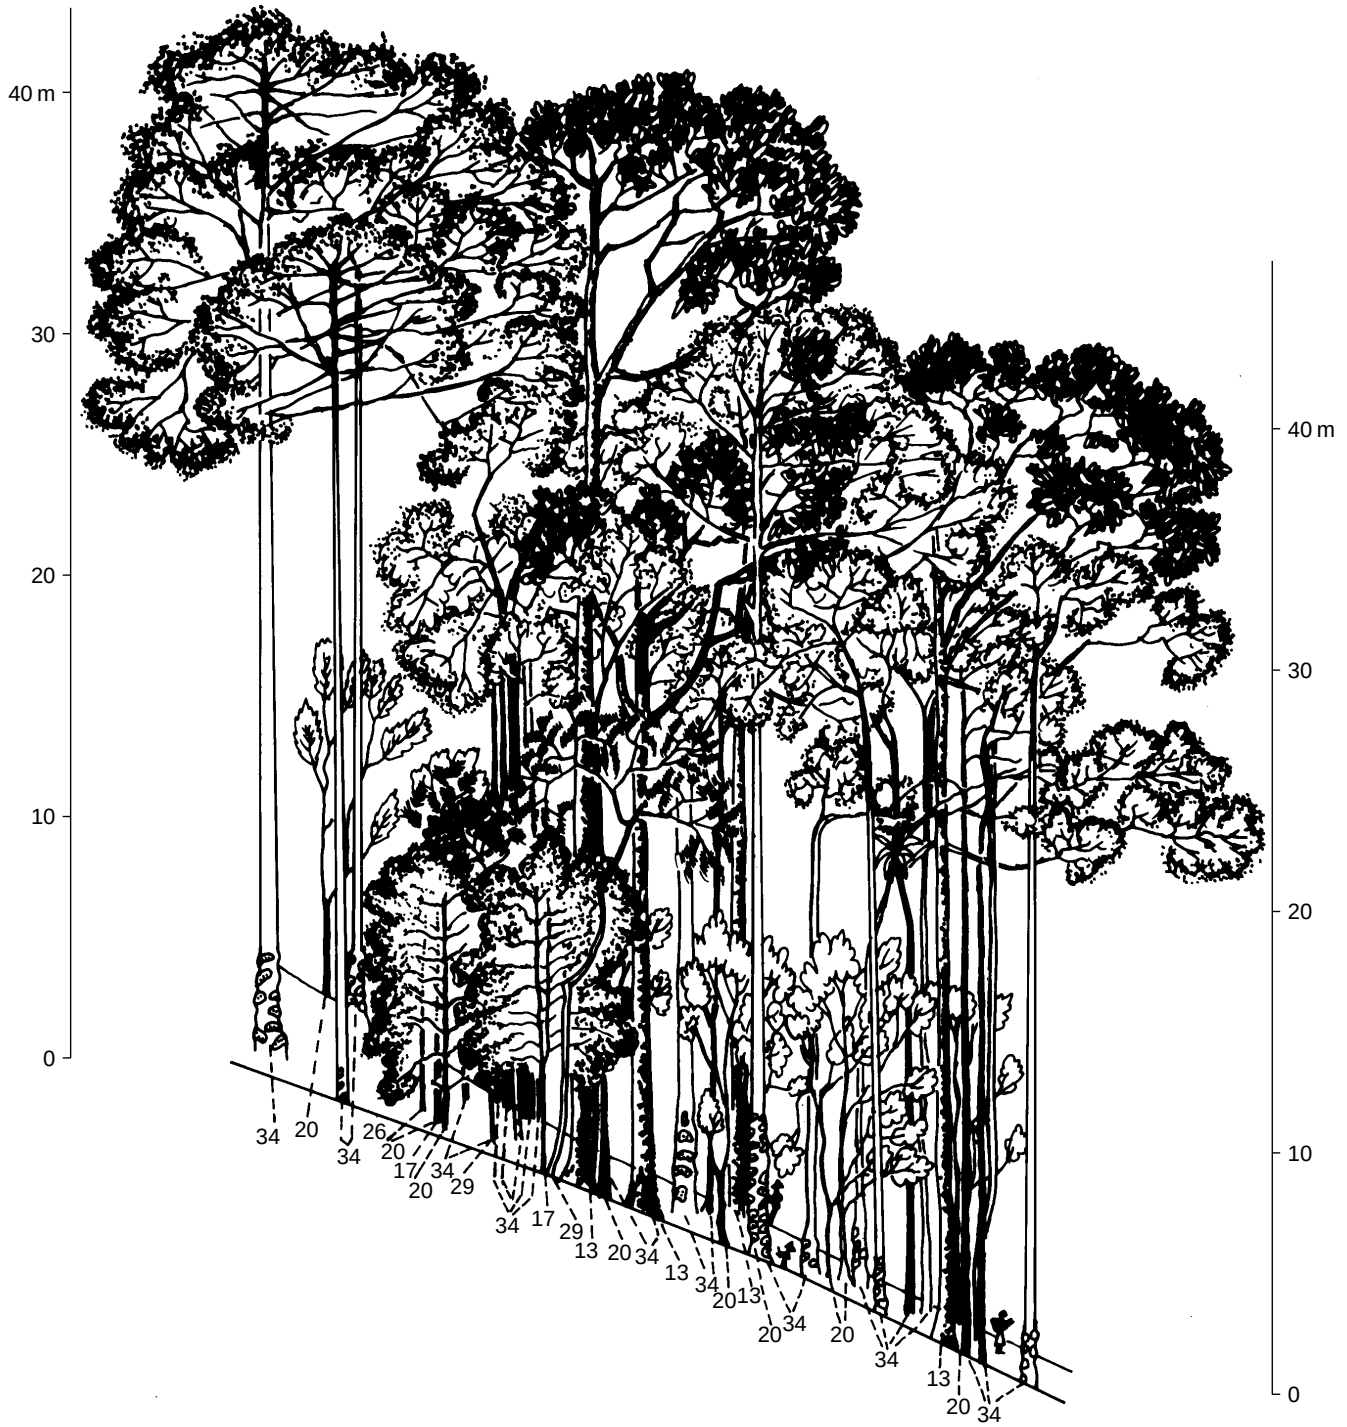

Figure 2 Architectural profile of a damar agroforest (20 × 30 m) in Sumatra where the damar trees are associated with fruit trees (durian, rambutan, mangustan, etc.). (Reproduced from De Foresta and Michon, 1993)

ICRAF has been promoting the use of powerful nitrogen legume species that also help in the recovery of degraded soils. Where there has been a surge of renewed experimental systems, effort is concentrated on the problem of improving fallow periods. Across the tropical world, most agroforestry experiments use the same limited number of exotic legume species. This involves the planting of soil-enriching legume species such as the well-known *Leucaena leucoceplala* during the early stages of fallow periods. But such exotic single species like *Leucaena leucoceplala* can

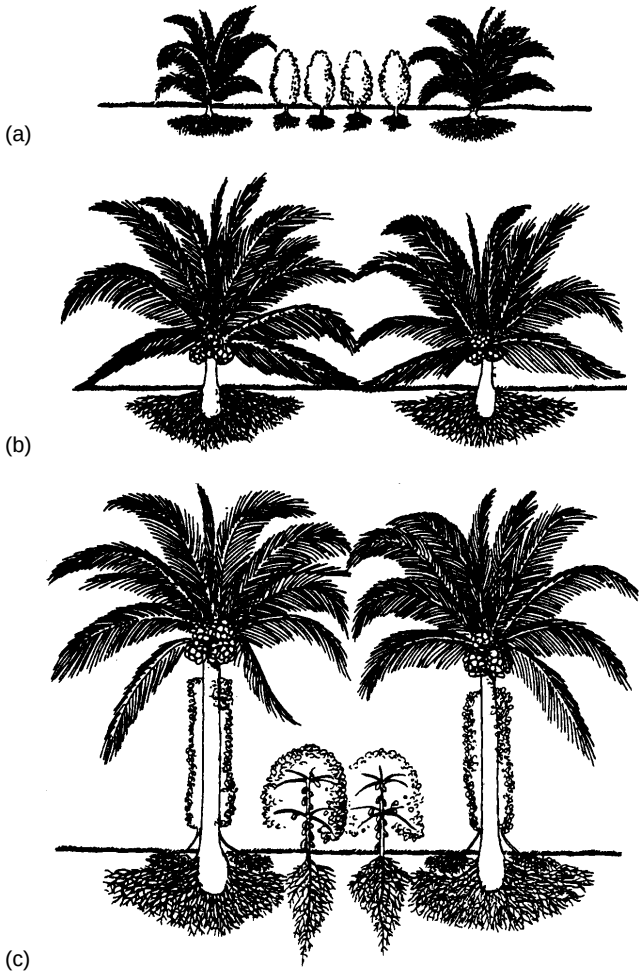

Figure 3 Schematic presentation of the growth phases of coconut palm indicating possibilities for crop combinations. (Reproduced from Nair, 1983). (a) Early phase, up to about 8 years; (b) middle phase, about 8–25 years, creating less than ideal conditions for underplanting; (c) later phase in which sufficient light enters the under-story to make conditions again suitable for a multi-storied combination of coconut, black pepper and cacao plantations

easily become invasive if not carefully controlled (its seeds from dehiscent (self-opening) pods have to be harvested each time). This is why it is important to use a variety of legume species, preferentially native ones that have the added value of contributing other useful products.

Additionally, experimental scientists in agroforestry have been concerned with the genetic improvement and vegetative propagation of an increasing number of indigenous forest tree species, well adapted to the local environment and not yet domesticated. A specific problem in breeding a potentially multi-purpose tree is that a single trait such as crop fruit production is usually selected for improvement whereas other qualities (shade, leaves for fodder, timber) may be ignored.

TEMPERATE AGROFORESTRY SYSTEMS

Finally, it should be pointed out that agroforestry systems are not confined to tropical regions but may also exist in temperate zones where long-term uses of trees have been incorporated into successful agrosystems. Examples are the sugar maple-based system in Southern Canada and Northeastern United States, and the modern Paulownia-wheat intercropping systems of China. Farmers have practiced agroforestry for a long time, together with sylvopastoral systems, forestry grazing, windbreaks or orchard intercropping. In temperate industrial countries, modern agriculture has experienced crises during which traditional cultures were homogenized and landscape was severely modified. The Chinese agricultural landscape also has numerous areas of monoculture, but always interspersed with mixed cropping areas, forming a highly complex mosaic. Additionally, this system is strongly linked to the cultural traditions that have supported China for millennia and that remain strong today among rural populations.

AGROFORESTRY AND GLOBAL CLIMATE CHANGE

Agroforesters have to cope with climate variations (seasons and year-to-year changes); they use numerous and multi-purposed plant species (and varieties). If 21st century climate is going to warm, advantages of the agroforestry systems, including biodiversity and the traditional practices that the local people utilize, will help them cope. However, scientists must be careful to keep enough genetic diversity within cultivars (especially in long-lived trees) when introducing improved selected plants in modern experimental agroforestry.

CONCLUSION

Agroforestry is a relatively new science and research is advancing strongly in developing countries, along with organic farming. Future research and development of agroforestry systems must include agronomic, environmental and economic aspects. It is no longer adequate to demonstrate biophysical increases in productivity without addressing environmental parameters within the socio-economic context of the people concerned. It should be admitted, however, that agroforestry is not a panacea for solving all problems. Agroforestry should be carried out in conjunction with other land-use systems in a mosaic of diverse spatial and temporal practices. It is the total economic value of the forest, natural or managed, that has to be kept in mind. Agroforestry is not a question of production in the abstract, but enriching the potential welfare of human beings around the world.

Aircraft Emissions

Ulrich Schumann

Institut für Physik der Atmosphäre, Oberpfaffenhofen, Germany

Aircraft emit gases and particles directly into the upper troposphere and lower stratosphere, mainly in Northern Hemisphere mid-latitudes, where they have an impact on atmospheric composition. These gases and particles alter the concentration of atmospheric greenhouse gases, including carbon dioxide (CO_2), water vapor (H_2O), ozone (O_3), and methane (CH_4). They may trigger the formation of condensation trails (contrails), increase cirrus cover and change other cloud properties, all of which affect the energy and water budgets of the atmosphere and hence may contribute to climate change at the regional and global scale.

The disturbances induced by global aviation cause an additional radiative forcing (heating) of the Earth- atmosphere system by aircraft of about 0.05 $W m^{-2}$ or about 3.5% of the total radiative forcing by all anthropogenic activities in 1992. The values are presently increasing both in absolute and relative terms. Nitrogen oxides (NO_x) emissions from current aircraft are calculated to have increased O_3 by about 6% in the region 30- 60 °N latitude and 9- 13 km altitude. Calculated changes in the total column of O_3 in this latitude range are approximately 0.4%. Calculated effects are substantially smaller outside this region. Emissions of NO_x into the stratosphere above about 20 km might cause a reduction of O_3. An order 1% reduction of O_3 in the stratosphere and a corresponding increase of ultraviolet (UV)-B radiation at the surface may occur if a large (1000 aircraft) eet of supersonic aircraft were to become operational.

Aircraft emissions near airports contribute to local air pollution. The emitted nitrogen oxides (NO_x) reduce the ozone (O_3) concentration in the immediate neighbourhood of the airport and, together with the emitted hydrocarbons, may induce additional O_3 several 10 km downstream from the airport by photochemical smog reactions. Outside the immediate neighbourhood of airports, in regions with high ground traffic and high population density, the emissions and the resultant smog are dominated by other forms of traffic such as motor vehicles, or by industry and domestic emissions. Noise induced by aircraft engines and aircraft structures during take-off and landing is often considered as a significant environmental problem.

TRAFFIC

Aviation is an integral part of the infrastructure of today s society. It plays a vital role for global commerce and private travel. Air traffic has grown strongly in recent decades, see Figure 1, faster than the economy as a whole. In 1997, 13 489 jet, 3213 turbo-prop, and 291 piston-engine commercial aircraft carried 1457×10^6 revenue passengers worldwide, on average over 1766 km distance per flight. The number of jet aircraft increased by 4.8% $year^{-1}$ from 1981 to 1997, turbo-props by 2.2% $year^{-1}$, while the number of aircraft with piston-engines is decreasing. The number of

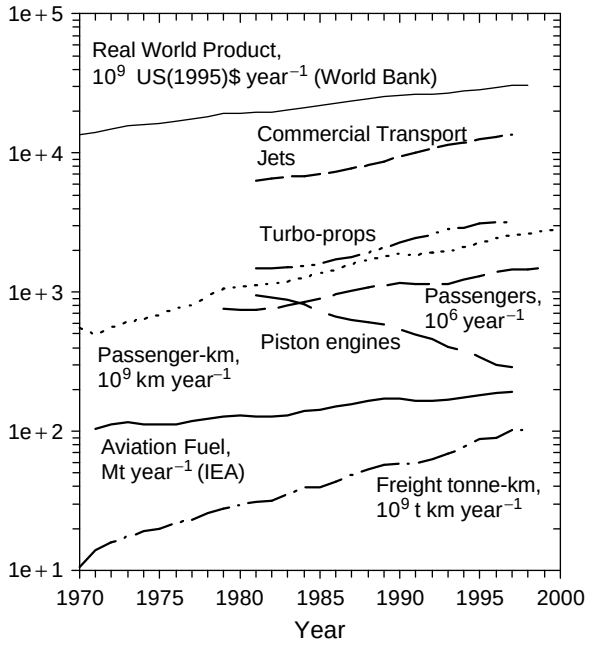

Figure 1 World aviation in the years 1970–1999: civil commercial transport aircraft (three types) registered in International Civil Aviation Organization, ICAO states, and traffic of commercial air carriers as reported by the ICAO (Montreal), aviation fuel production as reported by the International Energy Agency (IEA, Paris), together with the real world economic product (Worldbank, Washington, DC)

revenue passengers increased by 4.2% year^{-1} from 1981 to 1997. Passenger traf c increased by 5.3% year^{-1} to 2573 $\times$ 10^9 year^{-1} revenue passenger-kilometres, and freight traf- c by 7.8% year^{-1} to 103 $\times$ 10^9 freight tonne-kilometres per year in the same period. For comparison, the world economic output (gross national product, GNP, in market prices of 1995) grew by 2.4% annually on average in the years 1991 to 1998 (World Bank, Washington, DC, March 2000).

FUEL CONSUMPTION

Global air traf c consumed aviation fuels at a rate of 130 to 170 Mt year^{-1} during the year 1992 (i.e., about 5 6% of all petrol products), including a military fraction of about 18% (Intergovernmental Panel on Climate Change (IPCC), 1999). The upper bound fuel consumption value is the aviation fuel production reported by the IEA (International Energy Agency), the lower bound results from analysis of air traf c, and aircraft/engine speci c fuel consumption estimates. About 65% of the fuel is consumed at cruise altitudes between 10 and 13 km, see Figure 2. The largest fraction is consumed by wide-body aircraft on long-distance ights. Most of the emissions occur between 30° and 55 °N over the USA, Europe, and the North Atlantic. Globally the fraction of fuel burnt above the tropopause has been estimated to be about 30%. Over the North Atlantic the stratospheric fraction of fuel consumption is about 50% of the annual mean, with larger values during winter. The noon/midnight ratio of air traf c (in terms of fuel consumption) amounts to about 3 globally. Aviation fuel production grew by about 2.6% annually from 1981 to 1997, and was estimated to be about 200 Mt year^{-1} in the year 2000. The fuel consumption has grown at a slower rate than the traf c because of improved aircraft (engine and frame) technology, increased load factors of the aircraft, and a reduced fraction of fuel consumption for military purposes.

For the future, global passenger air travel, as measured in revenue passenger-km, is projected to grow by about 5 6% year^{-1} between 1990 and 2015, whereas total aviation fuel use, including passenger, freight, and military, is projected to increase by 3 4% year^{-1}, over the same period. The military fraction is expected to decrease to 7% in 2015.

EMISSIONS

In burning kerosene (a hydrocarbon mixture with about 13.8% hydrogen mass fraction) with air, engines emit mainly the greenhouse gases carbon dioxide (CO_2) and water vapor (H_2O) (Table 1). Minor emissions formed during combustion in the engine include nitric oxide (NO) and nitrogen dioxide (NO_2) (which together are termed NO_x, the emissions being measured in terms of mass units of NO_2), hydrocarbons (H_xC_y), carbon monoxide (CO), and soot. Soot includes around 10^{15} particles kg^{-1} of burnt fuel with typical diameters of 10 30 nm (Karcher, 1999). Kerosene contains about 0.8 (0.001 3) g sulphur kg^{-1} of fuel. During the combustion in the engines, this sulphur is converted to sulphur oxides (SO_x), mainly sulphur dioxide (SO_2), but partly into sulphur-trioxide (SO_3) and after some cooling and with H_2O, into sulphuric acid (H_2SO_4). The conversion fraction of fuel sulphur to H_2SO_4 in the young plume is in the range of 0.4% to about 10%.

Aviation contributes about 1.6 to 2.2% to the global anthropogenic CO_2 emissions of about 7000 Mt C year^{-1}, 10 to 13% of traf c-originating CO_2, and 2% of all NO_x sources. Other NO_x sources (in units of Mt NO_2 year^{-1}) include biomass burning (17.5), industry and surface traf c (72), microbial activities in soil (11.7), lightning (16.4), and stratospheric sources (2.1; Lee *et al.*, 1997). Aircraft emission amounts of CO and hydrocarbons are much smaller than other anthropogenic emissions and of little importance for air chemistry outside airports. The methane (CH_4) concentration at engine exit may be smaller than in the ambient air. Total aviation NO_x emissions increased faster than fuel consumption over recent decades because of higher

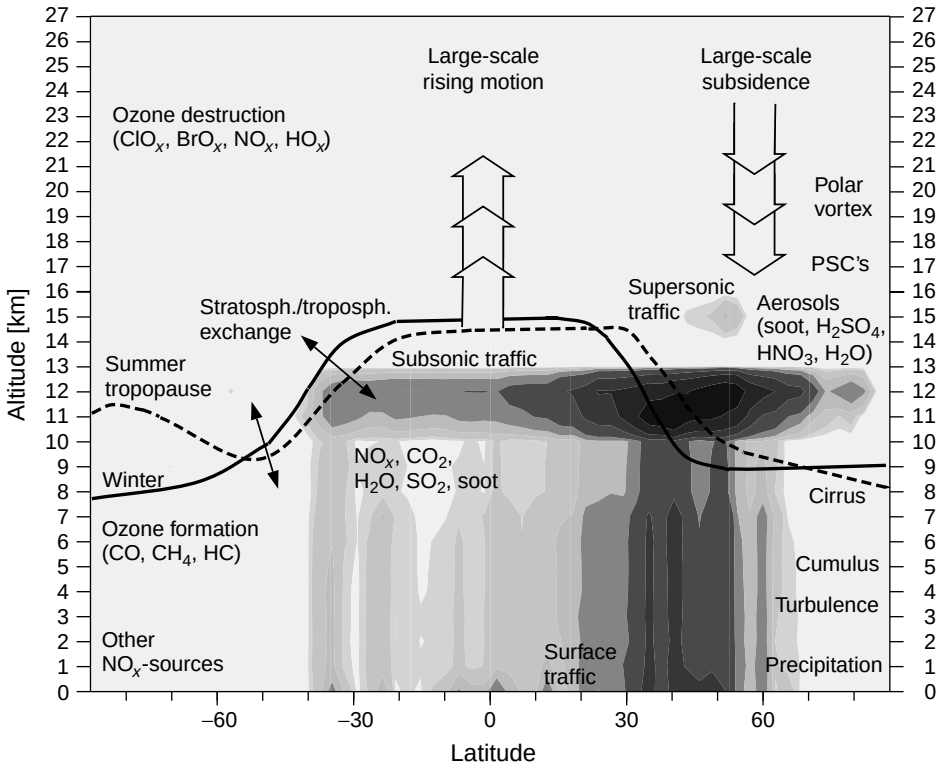

Figure 2 Mean altitude of the tropopause in June and December, and distribution of NO_x emission source rates from aircraft versus altitude and latitude (the emission rate is the larger the darker the shaded area), and indications of mean circulation and some relevant processes

Table 1 Consumed or emitted species, mean emission indices, i.e., mass of emissions per unit mass of burned fuel, for the fleet of aircraft in 1992, total emission rates due to aviation, and comparable emission rates. (Reproduced by permission of Intergovernmental Panel on Climate Change (IPCC), 1999)

Species	Emission index, g kg^{-1} (ranges)	Emission rate (1992) in Mt year^{-1}	Comparable emission rate, Mt year^{-1}	Comparable emission source
Kerosene		140 (139–170)	3140	Total petrol production
CO_2	3160	440 (430–540)	26 000–30 000	Total anthropogenic CO_2 emissions
H_2O	1230	176	45	Methane oxidation in the stratosphere
			525 000	Evaporation of H_2O from Earth's surface
NO_x	14 (12–16)	2	2.9 ± 1.4	Stratospheric sources
			90 ± 35	Total anthropogenic source
Soot	0.04 (0.01–0.1)	0.006	12	Combustion of fossil fuels and biomass
SO_2	0.8 (0.6–1)	0.12	130	Total source from burning fossil fuels
			20–100	Natural sources
			5.4, 8.0	Non-eruptive, eruptive volcanoes
CO	4 (2–6)	0.56	1500	Total anthropogenic sources
H_xC_y	0.6 (0.2–3.0)	0.2	90	Total anthropogenic sources

combustion temperature and pressure in more fuel-efficient modern engines. Other types of emissions decreased per unit of fuel consumption.

CHANGES IN AIR COMPOSITION

The gases and particles emitted by aircraft accumulate in the atmosphere near the flight routes, mainly in the northern mid-latitudes, depending on their residence time. Emissions into the lowermost stratosphere (see Figure 2), just above the tropopause get mixed mainly poleward and downward by the mean circulation, and leave the stratosphere by stratosphere-troposphere exchange processes (see Figure 2). Lower-stratospheric inert emissions reside there for an order of weeks to months. Some of the emissions have shorter residence times because of chemical conversions. For example, NO_x near the tropopause gets converted to nitric acid (HNO_3) within a few days or weeks. The NO_x concentration in the upper troposphere is about 1000 times lower than in urban regions, and the residence time for NO_x emissions near the ground is about ten times smaller than near the tropopause. Therefore, the relatively small amounts of aircraft emissions have notable effects on the NO_x concentration near the tropopause. Accumulations of aircraft emissions of NO_x are measurable regionally near main traffic corridors at least under low wind conditions (Schumann *et al.*, 2000). Increases of the concentration of small particles emitted from aircraft with similar residence times have also been measured near dense flight routes. CO_2 on the other hand, has a lifetime of the order of 100 years and gets distributed essentially over the whole atmosphere. Therefore, the effects of CO_2 emissions from aircraft are indistinguishable from the same quantity of CO_2 emitted at the same time by any other source.

The gases and particles emitted or formed as a result of aviation have an impact on climate both directly and indirectly. The direct effect is due to absorption and scattering of radiation. Indirect effects are many. They result from chemical or physical effects of the aircraft emissions on the gases and clouds, which act as greenhouse gases or radiative scatterers or influence clouds and precipitation, and influence the energy budget and the hydrological cycle on Earth.

CO_2

Concentrations of and radiative forcing from CO_2 today are those resulting from all anthropogenic emissions during the last 150 years. The atmospheric CO_2 concentration increased by about $80\,\mu mol\,mol^{-1}$ since 1850, and is responsible for a radiative forcing of $1.6\,W\,m^{-2}$. For an order of magnitude estimate, one assumes that $1\,W\,m^{-2}$ radiative forcing causes a global change in surface temperature of the order 0.3 1.0 K.

Aviation caused less than $1.4\,\mu mol\,mol^{-1}$, i.e., 1.2 1.7% of the total increase (Sausen and Schumann, 2000). This percentage is lower than the percentage for emissions (<2.4%) because aviation emissions have occurred mainly in only the last 40 years. The related CO_2 radiative forcing due to aviation fuel consumption in the past is $0.02\,W\,m^{-2}$. The corresponding increase in surface temperature is too small to be observable but is computed to be about 0.004 K. For a scenario used in Intergovernmental Panel on Climate Change (IPCC) (1999) with 3.2-fold increase in aviation fuel consumption from 1992 to 2050, one computes a CO_2-concentration increase of about $6\,\mu mol\,mol^{-1}$, causing a temperature and sea level increase of 0.025 K and 3 mm (Sausen and Schumann, 2000). Note that these are scenario calculations covering CO_2 effects only.

O_3

O_3 is a greenhouse gas, which is particularly effective within the tropopause region because of low temperature in this region and low thermal radiation emission at low temperatures. O_3 also shields the surface of the Earth from harmful UV radiation. This shielding increases to first approximation with the column of O_3 (most O_3 resides in the stratosphere). O_3 also acts as a biologically effective air pollutant at the Earth s surface.

O_3 in the stratosphere might get reduced when NO_x concentrations increase there. The photocatalytic cycles for NO_x in the stratosphere are similar to those by which halogen compounds (ClO_x and BrO_x) and hydroxyls (HO_x) cause catalytic O_3 destruction. However, NO_x also binds other O_3-destroying radicals and hence, additional NO_x reduces O_3 only above altitudes of about 20 km. In the troposphere and lower stratosphere, other photocatalytic cycles dominate, which cause oxidation of CO and CH_4 and other hydrocarbons, and cause O_3 formation at a rate which increases with the NO_x concentration at least up to a certain maximum of NO_x concentration (Brasseur *et al.*, 1998). The O_3 formation in the upper troposphere is controlled by the concentration of NO_x, but depends also on the availability of CO, hydrocarbons, and gases that provide sources for HO_x radicals such as O_3, H_2O and acetone. Hence, NO_x emissions from the present fleet of subsonic aircraft, flying essentially below 13 km altitude, cause O_3 increases, while the same emissions from a potential future fleet of supersonic aircraft, flying above 16 km, could cause O_3 destruction. Because of the much larger time scales of photochemistry of O_3 (on the order of weeks), the O_3 concentration change is spread more smoothly over the zonal belt downwind of and adjacent to the main flight corridors. The O_3 change is also notable at far distances from the corridors. Aircraft emissions of NO_x are more effective in producing O_3 in the upper troposphere than an equivalent amount of emission at the

surface. Also increases in O_3 in the upper troposphere are more effective in increasing radiative forcing than increases at lower altitudes.

The NO_x emissions from subsonic aircraft in 1992 are estimated to have increased O_3 concentrations at cruise altitudes in northern mid-latitudes by up to 6%, compared to an atmosphere without aircraft emissions (Intergovernmental Panel on Climate Change (IPCC), 1999). This change in O_3 concentration is of similar magnitude as the natural year-to-year variability. The impact on O_3 concentrations in other regions of the world is substantially less. These increases, on average, tend to warm the surface of the Earth. Computational studies with a global climate model show that aircraft-induced O_3 changes cause temperature changes, which are large enough regionally (order 0.2 K at some latitudes) to be distinguishable from climatic noise at the time scale of a few decades. It seems that aviation induced O_3 is particularly effective in heating the troposphere (Ponater *et al.*, 1999).

CH_4

CH_4 is also a greenhouse gas. Direct contributions from aircraft emissions to methane are unimportant, but NO_x increases in the upper troposphere lead indirectly to reductions of CH_4. The additional NO_x from aircraft enhances the oxidation cycle of CO, which causes local increases in OH radicals (*see* **OH Radical: is the Cleansing Capacity of the Atmosphere Changing?**, Volume 2). Such radicals are short-lived and react with CO both in warm and cold air masses; they react also with CH_4 but essentially only in warm air. The induced OH radicals in the cold upper troposphere reduce the concentration of CO at ight levels. CO has a lifetime of about two months, longer than typical vertical transport times in the atmosphere. Therefore, the CO reduction is felt also near the surface. Reduced CO abundance near the surface leaves more OH radicals from other sources to react there, in warm air masses, with CH_4. Hence, aircraft NO_x emissions indirectly cause a reduction of CH_4. The CH_4 concentration in 1992 is estimated to be about 2% less than that in an atmosphere without aircraft (Intergovernmental Panel on Climate Change (IPCC), 1999). This aircraft-induced reduction of CH_4 concentration is much smaller than the observed overall 2.5-fold increase since pre-industrial times. The reductions in CH_4 tend to cool the surface of the Earth.

H_2O

Water vapor is a greenhouse gas and of chemical importance. The amount of H_2O emitted by aviation is much smaller than the amount of water evaporating at the Earth s surface but comparable in magnitude to the amount of water resulting from CH_4 oxidation in the stratosphere (Table 1). Most subsonic aircraft H_2O emissions are released in the troposphere where they are removed by precipitation within 1 2 weeks. Some fraction of H_2O emissions is released in the lower stratosphere where it can build up to larger concentrations. Because H_2O is a greenhouse gas, these increases tend to warm the Earth s surface. Additional H_2O in the stratosphere may also induce hydroxyl radicals and reduce O_3 either directly or indirectly by forming polar stratospheric clouds, which cause halogen activation. However, for subsonic aircraft, these effects are small compared to the other climatic or chemical effects of aircraft emissions (Intergovernmental Panel on Climate Change (IPCC), 1999).

SULPHATE AND SOOT AEROSOLS

Besides soot, large numbers (about $2 \times 10^{17}\,kg^{-1}$ fuel) of small (radius 1 5 nm) liquid particles are formed in the exhaust plumes of cruising aircraft. These new particles initially form from H_2SO_4, chemi-ions, condensable hydrocarbons, and H_2O; they grow in size by coagulation with other particles and by uptake of H_2O and other condensable gases. Chemi-ions are charged molecule clusters formed during combustion. Charged particles enhance the coagulation ef ciency (Karcher, 1999). The fuel sulphur content has little in uence on the conditions for contrail formation but has strong impact on the size of newly formed particles. The particles from aviation add to the atmospheric aerosol and impact cloud formation. The number of ice particles formed in the young contrail varies by a factor of about 3 for a factor 500 change in fuel sulphur content.

Subsonic aircraft emissions near the tropopause at northern mid-latitudes are a signi cant source of soot and sulphate aerosol concentrations, at least by number. Aircraft generate far less aerosol mass than that emitted and produced at the Earth s surface or by strong volcanic eruptions (Table 1). Aircraft emissions injected directly at 9 12 km altitudes are more important than similar surface emissions because of longer atmospheric residence times and lower background concentrations of pollutants in the upper troposphere. The direct radiative forcing by the accumulated aerosol is small compared to those of aircraft induced gases. The chemical effects of soot and other particles from aviation on O_3 by means of heterogeneous chemistry, and the physical effects of aerosol on cloud properties are not well known, but may be important.

CONTRAILS

Contrails are visible line clouds, see Figure 3, which form from H_2O emitted by aircraft ying in suf ciently cold air. Contrail formation, according to the Schmidt-Appleman

Figure 3 Contrails of various ages at high ambient humidity. (Photo: U. Schumann)

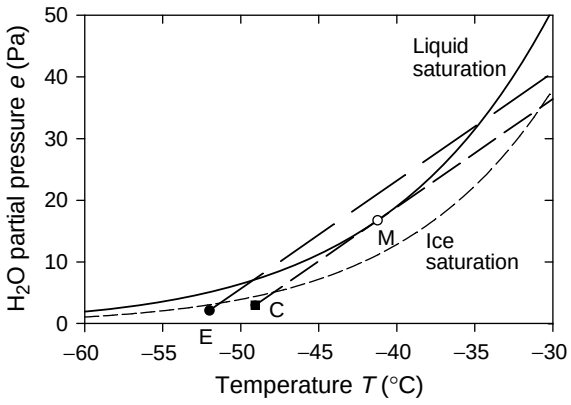

Figure 4 Mixing lines (dashed lines) and saturation curve over liquid water (full) and ice (dashed) in a diagram of partial water vapor pressure e versus temperature T. The mixing lines are plotted for environmental conditions with temperature T in the environment below (point E) and at (point C) the threshold temperature. At point M liquid saturation is reached during mixing under threshold conditions. Contrails remain short if E is below the ice-saturation curve and contrails may grow and persist if E is above ice saturation

criterion (Schumann, 1996), is due to the increase in relative humidity that occurs in the engine plume during mixing of the warm and moist exhaust gases with the colder ambient air, see Figure 4. When the humidity reaches liquid saturation in the young plume behind the aircraft, liquid droplets form, mainly by condensation of H_2O on exhaust particles, which then soon freeze to form ice particles. In the absence of aircraft-induced particles, water in the moist aircraft plume would condense on ambient aerosol entrained into the plume, causing less but larger ice particles, with smaller optical thickness and less radiative impact. Contrails typically form at temperatures below about -35 to $-60\,^{\circ}\mathrm{C}$, see Figure 5, but the actual value

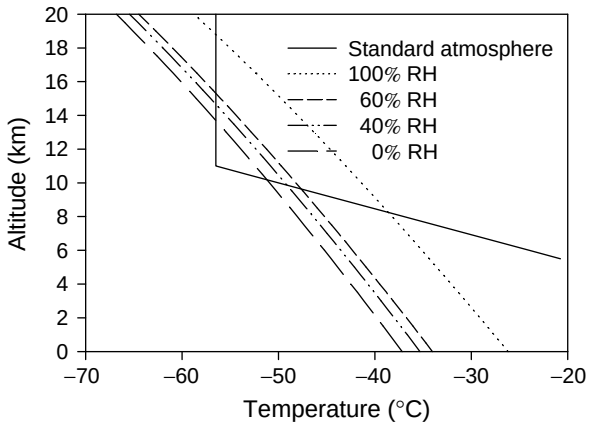

Figure 5 Threshold temperature for 0, 40, 60, and 100% relative humidity over liquid saturation (RH) for overall propulsion efficiency $\eta = 0.3$, kerosene fuel with water vapor emission index $EI_{H_2O} = 1.223$, and combustion heat $Q = 43.2\,\mathrm{MJ\,kg^{-1}}$, and temperature profile of the mid-latitude standard atmosphere versus altitude, z

increases with ambient relative humidity and with the parameter:

$$G = \frac{EI_{H_2O} p c_p}{[\varepsilon Q(1-\eta)]}$$

which is the slope of the mixing line in the diagram of water vapor partial pressure versus temperature, Figure 4. Hence the threshold temperature for contrail formation depends also on fuel and combustion properties in terms of the emission index EI_{H_2O} of water vapor and the combustion heat Q, on ambient pressure p at flight level, on the specific heat capacity of air c_p, the ratio $\varepsilon = 0.622$ of molar masses of water vapor and air, and on the overall efficiency η of the aircraft/engine system at cruise.

Contrails evaporate quickly when forming in dry ambient air. The fractional global coverage by these contrails is less than 0.001% and hence of no importance to the climate. Contrails persist, sometimes for hours, and grow when the ambient air is very humid with humidity above ice saturation. Ice particles in such persistent contrails grow by uptake of H_2O from the surrounding air. About 10 20% of all jet aircraft flights occur in air masses that are humid enough to cause persistent contrails. Ice-supersaturation in these regions is often too small to allow cirrus to form naturally, so aircraft act as a trigger to form cirrus clouds.

Contrail clouds can be identified and discriminated from natural cirrus clouds in satellite data based on their linear shape, see Figure 6, at least up to some age depending on the ambient conditions (Mannstein *et al.*, 1999). In 1996 and 1997, satellite data reveal that linear persistent contrails cover about 0.5 0.7% of the sky at noon over Europe in the annual average. This represents a lower bound for the actual

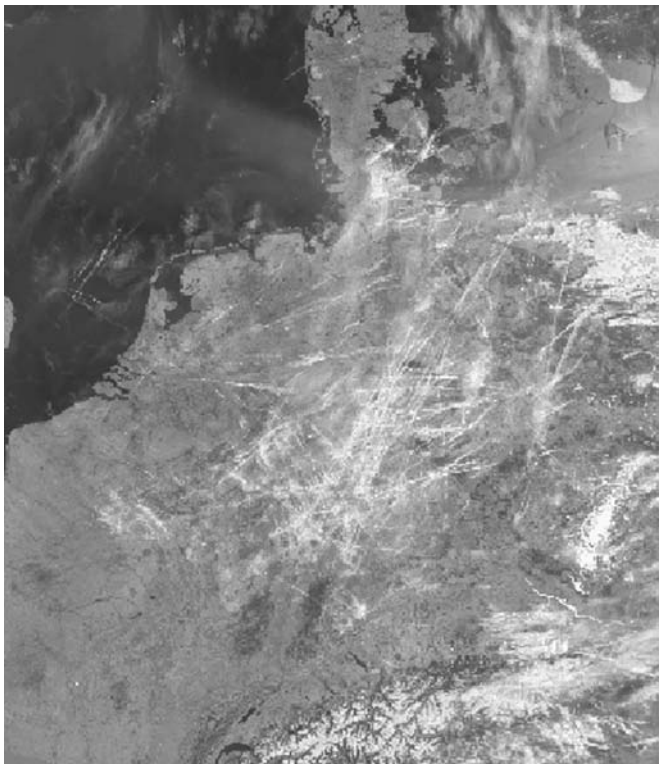

Figure 6 Contrails over mid-Europe on May 5, 1995, 7 : 43 UT, processed from NOAA-12 AVHRR data (as explained in Mannstein *et al.*, 1999). Photo: DLR/DFD

contrail cover. The fraction of cirrus clouds with non-linear shape which originated from old contrails or from aircraft induced particles is unknown. The satellite data indicate a night-time contrail cover which is about 1/3 of that during daytime.

The mean global cover by linear contrails has been estimated to be 0.1% (possibly 0.02 0.2%) for 1992. The contrail cover grows faster with traffic than aviation fuel consumption because air traffic increases mainly in the upper troposphere where contrails form preferentially. Future improvements in the overall propulsion efficiency η will increase the threshold temperature of contrail formation and, hence, the contrail cover.

Contrails cause a positive mean radiative forcing at the top of the atmosphere, in particular during night and over warm and bright surfaces. They reduce both the solar radiation reaching the surface and the amount of longwave radiation leaving the Earth to space. Contrails reduce the daily temperature range at the surface and cause heating of the troposphere. The radiative effects of contrails depend mainly on their coverage and optical depth, both of which are still not well known.

For 0.5% additional cirrus cloud cover regionally, a regional surface temperature increase of the order 0.05 K is expected. Such an increase can hardly be discriminated from natural variability. However, an increase of mean cirrus cloudiness in regions with heavy air traffic from typically 20% to 25% (i.e., by 5% cloud cover) has been found in models to cause a significant regional temperature change of order 1 K. The daily temperature range at the ground decreases with increasing cirrus cover but only little because of stronger sensitivity to lower atmospheric humidity.

CIRRUS CLOUDS

Some correlation between soot and ice particle concentrations have been measured in cirrus clouds which indicates an aviation impact on ice particle formation. Contrails trigger cirrus clouds in air masses which are sufficiently humid to let contrails spread but not humid enough to let cirrus form naturally. On average an increase in cirrus cloud cover tends to warm the surface of the Earth. More than 20% of the Earth is covered with cirrus clouds. Long-term observations of cloud frequencies at some meteorological stations and some satellite data indicate strong increases of the frequency or cover of cirrus clouds (Boucher, 1999; Intergovernmental Panel on Climate Change (IPCC), 1999), for unknown reasons. The increases are particularly large in regions with high air traffic density. The global trends suggest a cirrus cover increase of up to 0.2% since the beginning of jet aviation, in addition to the 0.1% cover by line-shaped contrails. The cirrus cover changes cannot be conclusively attributed to aircraft emissions or any other causes.

CLIMATE EFFECTS

The radiative effects of the emitted greenhouse gases and particles, of changes in O_3, and of changes in cloudiness, can be compared to each other and to climate effects from other causes by using the concept of radiative forcing. *Radiative forcing* is de ned as the net radiative ux change at the top of the atmosphere calculated in response to a perturbation, such as a change in gas concentration or cloud cover (with the stratosphere thermally adjusted to the change in radiative uxes) (*see* **Radiative Forcing**, Volume 1). A positive net ux change represents an energy gain and, hence, a net heating of the Earth System. The global mean climate change of surface temperature at sea level is approximately proportional to the global average radiative forcing. However, the strong concentration of air traf c at the northern mid-latitudes may cause larger regional climate changes. Up to now, such regional changes are not detected.

The radiative effects resulting from aircraft engine emissions are summarised in Figure 7 (Intergovernmental Panel on Climate Change (IPCC), 1999). The uncertainty associated with several of these effects is large. The best estimate of the radiative forcing in 1992 by aircraft is

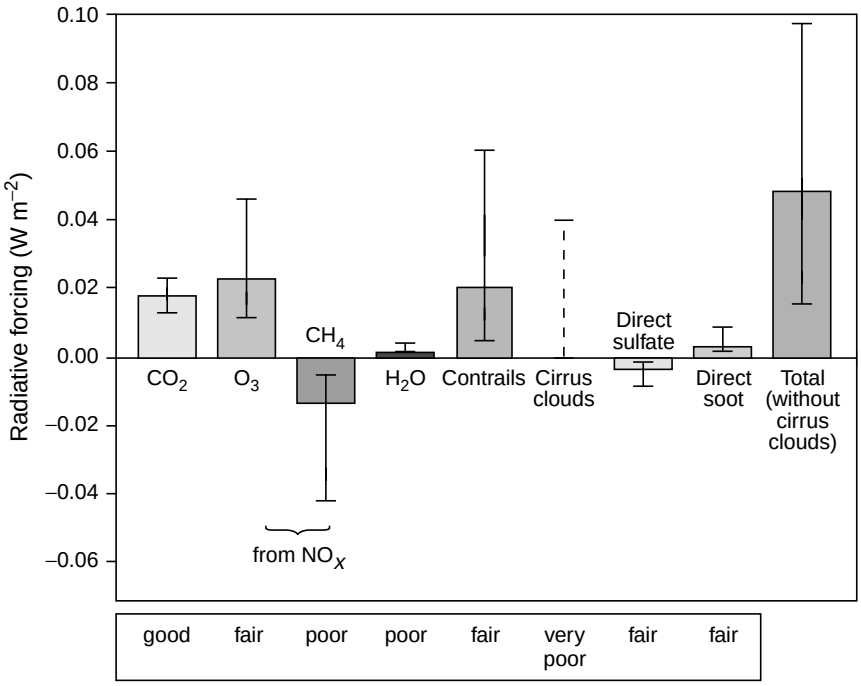

Figure 7 Radiative forcing (W m^{-2}) due to aircraft emissions in 1992 (Intergovernmental Panel on Climate Change (IPCC), 1999). The columns indicate the best estimate of forcing. The error bars denote the range within which the best-estimate value is expected with a 2/3 probability. The available information on cirrus clouds is insufficient to determine either a best estimate or an uncertainty range; the dashed line indicates a range of possible best estimates. The estimate for total forcing does not include the effect of changes in cirrus cloudiness. The evaluations below the graph (good, fair, poor, very poor) are a relative appraisal associated with each component and indicates the level of scientific understanding. (Reproduced by permission of Intergovernmental Panel on Climate Change (IPCC), 1999)

0.05 W m^{-2} or about 3.5% of the total radiative forcing by all anthropogenic activities. The overall radiative forcing by aircraft (excluding that from changes in cirrus clouds) is a factor of 2 4 larger than the forcing by aircraft CO_2 alone.

In the future, for a reference scenario with a 6.7-fold increase in traffic and about a 3-fold increase in fuel consumption from 1992 to 2050, the Intergovernmental Panel on Climate Change (IPCC) (1999) reported a computed radiative forcing by aircraft in 2050 of 0.19 W m^{-2} (3.8 times the value in 1992). For the range of scenarios considered in that assessment, the forcing is projected to grow to 0.13 to 0.56 W m^{-2} in 2050, i.e. 2.6 to 11 times the value in 1992. These estimates of forcing combine the effects from changes in concentrations of CO_2, O_3, CH_4, H_2O, line-shaped contrails, and aerosols, but do not include possible changes in cirrus clouds.

The emissions of NO_x cause changes in CH_4 and O_3, and their influences on the radiative forcing are of similar magnitude, but of opposite sign. Changes in tropospheric O_3 are mainly in the Northern Hemisphere, while those of CH_4 are global in extent so that, even though the global average radiative forcings are of similar magnitude and opposite in sign, the latitudinal structure of the forcing is different so that the net regional radiative effects do not cancel.

The climatic effects of aircraft are superimposed on those caused by anthropogenic emissions of other greenhouse gases and particles, and on the background natural variability. It has not yet been possible to separate the aviation effects in observed climate parameters, such as surface temperature, from those of other natural or anthropogenic disturbances.

ULTRA-VIOLET RADIATION EFFECTS

Besides being a greenhouse gas, O_3 provides a shield against solar UV radiation. The calculated total O_3 column in northern mid-latitudes due to aviation is computed to be about 0.4% in 1992 (Intergovernmental Panel on Climate Change (IPCC), 1999). The increase in O_3 induced by subsonic aircraft decreases the UV radiation. The *erythemal* dose rate, defined as UV irradiance weighted according to how effectively it causes sunburn, is a maximum at northern mid-latitudes and is estimated to have been decreased by aircraft in 1992 by about 0.5% at 45 °N in July. The aircraft effect on UV is small compared to that caused by other O_3 changes.

RADIATIVE FORCING AND UV RADIATION EFFECTS OF SUPERSONIC AVIATION

About 13 supersonic aircraft of type Concorde were in operation until the accident in Paris on July 25, 2000. Their effect on the global atmosphere can be neglected compared to the effects of the far larger fleet of subsonic aircraft. Plans for a new fleet of supersonic aircraft have been discussed but no definite decision has been made to develop such a fleet (Intergovernmental Panel on Climate Change (IPCC), 1999). Supersonic aircraft would cruise at an altitude of about 16 24 km, would emit CO_2, H_2O, NO_x, SO_x, and soot directly into the stratosphere, and contribute to changes in stratospheric O_3, other trace gases and aerosols. Supersonic aircraft consume more than twice the fuel per passenger-km compared to subsonic aircraft. The radiative forcing of civil supersonic aircraft is estimated to be about a factor of 5 larger than that of an equivalent fleet of subsonic aircraft. The calculated radiative forcing of supersonic aircraft depends on the treatment of H_2O and O_3 in models which are difficult to simulate accurately. The effect of introducing a fleet of 500 civil supersonic (Mach 2.4, $EI_{NO_x} = 5\,g\,kg^{-1}$) aircraft is to reduce the stratospheric O_3 column in the Northern hemisphere by -0.4% (range -2.5 to $+0.5\%$, Kawa *et al.*, 1999), and to increase erythemal dose rate by a similar amount.

UNCERTAINTIES

Considerable progress has been made in recent years in quantifying the impact of aircraft emissions on the atmosphere. However, the scientific uncertainties are generally large. The state of scientific understanding of the radiative forcing of the various emissions has been evaluated by the Intergovernmental Panel on Climate Change (IPCC) (1999) as indicated in Figure 7. The evaluation is based on the evidence available, the degree of consensus in the scientific literature, and the scope of the analysis. The error bars and the scientific uncertainty are largest for the complex impact of NO_x on CH_4 reduction, for contrail cover and contrail optical depth, and, in particular, for the indirect effects of aviation on cirrus cloud cover and changes in cirrus properties. The figure accounts for global effects only. More work needs to be done to assess the impact of aviation on the climate in the northern mid-latitudes, where most of the air traffic takes place.

Animal Production, Feedlots, and Manure Problems in the US (Agriculture, Intensive)

Claudia Copeland
US Library of Congress, Washington, DC, USA

Managing the environmental effects of intensive animal rearing and feeding operations is a problem confronting the livestock industry. These facilities, which include con ned feeding operations and feedlots, are a specialized part of the livestock production process, largely separate from cropland agriculture. Manure and waste-handling and disposal problems from intensive animal production are receiving attention as these facilities increase in size and the effects of these problems reach beyond the industry.

The US population of animals in livestock production being raised to feed Americans and other consumers worldwide is very large. Waste produced by these animals is a valuable soil amendment and source of crop nutrients, when applied to land in proper amounts (the traditional waste management approach). However, if not properly used or disposed, or if applied in amounts that exceed plant needs, animal waste or its residuals can leach through soil to contaminate ground water or can be transported by runoff to pollute surface waters. Thus, as animal production has intensi ed concentrating more animals on individual farms, a growing challenge for agriculture is nding suf cient land to dispose of manure, or nding economic alternatives, especially if the supply of land for disposal is insuf cient. The parallel challenge for policymakers is determining if the environmental impacts of animal waste management are signi cant enough to require new remedies and, if so, what strategies are appropriate.

These issues have become prominent in US debates about agricultural and environmental policy. Beyond local and national borders, there are broader potential impacts, as well, re ected in concerns that the trends in livestock production practices and impacts on water and air quality observed in the US are being repeated elsewhere.

OVERVIEW OF ANIMAL AGRICULTURE

Livestock includes cattle (beef, dairy and veal), swine (hogs and pigs), poultry (chicken and turkeys), and sheep and lambs. Livestock is a large component of the farm economy in the US, contributing nearly half of the cash receipts of all US agriculture in recent years. The populations of animals are very large. In 1992, the US inventory of livestock was over 77 million cattle and calves, about 60 million swine, and almost one billion broilers. The inventory gradually shifts in response to changing market conditions and consumer preferences. Changes in geographic location of animals and how they are raised re ect economic considerations, business relationships, and changing technology. These changes have contributed to low prices of food protein globally and led to increasing concerns about several topics, including environmental effects.

Concentration

Livestock production in the US continues to have fewer producers operating at fewer sites. Such concentration offers economies of scale and depends increasingly on modern technologies and better information. This concentration started rst in the poultry industry about 40 years ago, and it is now the most concentrated segment. Broiler production in the US nearly tripled between 1969 and 1992, while the number of farms with broiler houses dropped by 35%. The concentration process has been similar for cattle feed operations and for the dairy industry: overall, the number of dairy farms dropped from 1988 to 1998 by 20%, while the average herd size increased by more than 50%. The US swine inventory has climbed by about 18% since the mid-1980s, while the number of swine farms dropped by 72%. The largest farms have grown larger, so that now, farms with an inventory of at least 1000 head make up less than 3% of the farms, but produce 60% of the swine.

Integration

Growing concentration is an element of broader changes often referred to as industrialization. Trends in farm organization and operation include not only fewer farms of a larger average size, but also vertical integration as farmers enter contracts with processors, or integrators. Under these contracts, producers raise the livestock while integrators actually own the animals, assume marketing risks, and may provide medicine, feed and technical expertise as well. Generally, vertical integration has increased the volume and certainty of supply and improved the market characteristics of the livestock. Producers forgo the risks and uncertainties of the marketplace by becoming contract growers, and as more production comes within these types of relationships, marketing opportunities may decline for those who do not choose to or are unable to participate. In economic terms, ef ciencies are gained for both producers and integrators at the expense of non-participants.

The overall livestock sector has grown since the 1980s, in part to serve expanding demand for protein in a more af uent world. For example, the US has become the largest beef-exporting nation in the world, with between 16 and 20% of world trade in recent years. Swine trade is similar, growing by an annual average of 4% since 1989; the US now accounts for almost 20% of the world s pork exports.

WASTE FROM ANIMAL AGRICULTURE

Animal wastes are predominately solid and liquid manures, but also include used bedding, spilled feed, and dead animals. Manure production in the US is estimated to be almost 112 million tons (dry matter) annually (113.8 million metric tons), or, 13 times more (on a dry-weight basis) than human sanitary waste production. Production varies not only with the animal type, but also with such factors as feed ration, health, animal age, and climate. Trends in the livestock sector, such as increased animal con nement (rather than pasturing) and improved feeds, have increased the amount of manure produced per animal and changed the composition. The larger volume per animal combined with concentration of more animals at a site compounds storage and disposal dif culties for farmers.

Animal waste contains nutrients, including nitrogen, phosphorus, and potassium. Nutrients can be valuable for crops, but their oxygen-demanding characteristics can cause water quality problems. Waste can also contain organic solids, trace heavy metals, salts, bacteria, viruses, other microorganisms, and sediments.

Farmers manage manure and related wastes in many different ways. Manure may be collected at temporary storage facilities (including stacks, ponds and tanks) until it can be treated or utilized. Waste may be treated to convert it to a more useful resource, usually by concentrating the beneficial constituents and decreasing the total volume.

Lagoons are the most common treatment facility. In a lagoon, the manure undergoes continuous anaerobic decomposition. Failure of lagoons and the resulting waste spills have brought much of the recent critical attention to animal agriculture, and some have called for phasing out lagoons. Other types of treatment facilities include composters, solid separators, and settling basins. Holding capacities of storage and treatment facilities are recommended based on the estimated time period the volume of waste must be retained. For example, waste should not be spread while the ground is frozen, or it will be washed into surface waters, so farms in locations where winters are long need a greater storage capacity. The management process ends when the waste is transferred and used. The most common use, by far, is to spread it across the farm fields as a soil amendment and a nutrient supplement. The manner in which it is spread can have environmental implications; for example, spray irrigation has been associated with environmental problems in some situations, while cultivation into the soil generally minimizes that potential.

Manure as an Agricultural Asset

Manure can be a valuable asset for agriculture, generally as a supplement to, or partial substitute for commercial fertilizers. Manure nutrient values, however, vary considerably and any supply of manure must be assessed to determine application rates. Commercial chemical fertilizer, by contrast, has consistent content, with that information supplied by the manufacturer. Also, nutrients from manure are not all immediately available.

A better way to view manure is as a soil amendment that improves many of the physical and chemical properties, as well as the nutrient values, of soil by adding organic material and improving soil structure and the ability to hold water and retain nutrients. These benefits are considerable, in terms of nitrogen and phosphorus needed by crops, plus the added benefits of improved soil quality, decreased runoff and soil erosion potential, and improved soil moisture, or offsetting costs associated with processing, transportation, and management.

Disposal Problems

Disposal has become more difficult for US producers because operations are larger; thus, there is more waste at a single site, and less land is under the control of these operators. Many of the largest US farms lack the capacity to manage manure on the land under their direct control. These difficulties have been compounded by increased concerns about water quality and other problems that may originate with intense and concentrated livestock farms.

In the US, animal waste accumulates unequally because of geographic concentration of livestock, and in many watersheds, the amounts of manure nitrogen and phosphorus generated exceed amounts needed to satisfy crop uptake/removal requirements. Data on manure production in 1997 indicate a significant potential for excessive nutrients, if all manure were spread on land. Manure nitrogen available for application to cropland and pastureland exceeded the potential for crop uptake by 57%. Likewise, manure phosphorus exceeded the potential for crop uptake and pastureland application by 65%. Estimates are that the number of US counties with excess manure production that have the potential to cause water quality problems more than doubled from 1982 to 1997.

Even when farmers control adequate land, proper disposal can still be a problem. The manure must be assessed for its nutrient value, then transported to the site, and spread in the proper amounts; each step is an expense for farmers. Producers often determine application rates based on crop needs for nitrogen. However, if application rates supply the needed nitrogen, there will be occasions when the amount of phosphorus or potassium applied will be excessive, especially after several successive years of application. Soils in areas with concentrated animal operations may accumulate excessive amounts of phosphorus, which normally binds to soil particles, but when particles become saturated, excess phosphorus enters ground water or nearby surface waters.

Manure management problems appear less substantial in the US than in some parts of Europe, especially the low countries, and some European countries are exploring options for addressing this problem. For example, in the Netherlands, where phosphorus saturation is generally believed to be the most serious problem, programs to stabilize manure production and application started in 1987, and since 1991, manure application rates have been declining. The Dutch policy goal is to reach an equilibrium fertilization rate by 2010, when the supply of nutrients from manure plus fertilizer is to be in balance with crop utilization and other losses.

Waste Disposal Options

Alternatives for disposing of manure, other than by land application, are receiving increased attention. The constituents and moisture content of the manure are important

in determining which disposal techniques to use. Shipping costs constrain many options because manure is of low economic value on a volume or weight basis, so it is uneconomic to ship it for long distances unless the waste can be concentrated to decrease the volume or increase the value.

Options under study include composting, burning, and biotech changes to feed supplies that alter the characteristics of the waste. Composting uses microorganisms to turn wastes into relatively stable and odorless material that can be used or sold as a soil amendment. Burning can be used to generate energy, as is done at a power station in East Anglia, UK, but there are limitations. For example, one ton of poultry litter contains about the same amount of energy as 80 US gallons (302.8 liters) of home heating oil, but has the same volume as about 500 US gallons (1892.7 liters). The residue of burned manure is about 10% of the original volume, and contains little of the original nitrogen and sulfur but most of the phosphorus that was initially present. A biochemical change that has received attention is adding phytase (an enzyme) to feed. It has been shown to remove 25% to 40% of the phosphorus and 10% of the nitrogen excreted by causing the animals to use nutrients more efficiently. Phytase does have a cost and must be added to feed. Still other options include converting the waste to fuel and energy, using industrial processes to convert the waste to other useful products, and using it as a feed supplement.

Such approaches are hard to apply widely because of various combinations of physical limitations, high costs, lack of knowledge or management skills by the producer, unfamiliar or untested technologies, and other factors. The costs and difficulties of storing and handling may be the most common constraints.

ENVIRONMENTAL AND PUBLIC HEALTH CONCERNS

In the US, agriculture is believed to be the leading source of water quality impairment in rivers and lakes, affecting 70% of impaired river lengths (waters that fail to meet applicable standards of water quality) and 48% of impaired lake areas. In estuaries, agriculture affects nearly 30% of impaired acres/hectares. In a 1996 assessment, in 22 states that specifically evaluated agriculture s impacts on rivers and streams, animal feedlots and animal holding areas were estimated to be the principal pollutant source in 20% of waters impaired by agricultural practices.

Animal feeding operations have been shown to cause significant environmental and public health problems, including nutrient enrichment of surface and ground waters, contamination of drinking water supplies (with e-coli, for example), fish kills, and odors. Animal waste, if not properly managed, can be transported by water over the surface of agricultural land to nearby lakes and streams. There, the nutrients in animal waste can reduce the oxygen content of the water, leading to algal blooms, fish kills, and threats to other wildlife. Catastrophic events, such as spills from livestock waste lagoons, have occurred in nearly every US state. Solids deposited in water bodies can accelerate eutrophication by releasing nutrients over extended periods. Leaching from manure storage lagoons and percolation through the soil of fields when animal waste is applied has resulted in nutrient contamination of groundwater resources.

Although animal waste is not the only source of pathogens in surface waters, it has been responsible for shellfish contamination in some coastal waters. Closure of shellfish beds and recreational beaches can be necessitated by high fecal coliform counts, both from animal waste runoff and discharge of improperly treated sewage. Animal diseases also can be transmitted to humans through contact with animal feces.

Atmospheric deposition of nitrogen from animal operations is also an environmental concern. This occurs when nitrogen in liquid waste is volatilized as ammonia (NH_3) from anaerobic (oxygen-deprived) lagoons, causing ammonia to evaporate. Volatilization also occurs after land application. Once in the atmosphere, it is converted to forms that are redeposited within 80 160 km on land or in surface waters. These forms of nitrogen are water-soluble, meaning that the nitrogen can adversely affect water quality much like nitrogen fertilizer if it enters a stream as direct surface runoff. Atmospheric transport broadens the environmental dimensions of animal waste management from local to national and even global.

Odor is the most controversial nuisance problem associated with feedlots, and is generally related to manure handling and spreading on fields. Other potential odor sources include wet feed and the decomposition of dead animals. The odors consist of gases, such as ammonia, hydrogen sulfide, methane, and organic compounds produced during decomposition of manure. Although some of the gases are known to be harmful or toxic in large amounts, the principal effect upon humans is annoyance or nuisance. Solutions to odor problems generally involve setbacks, buffers, and other land use planning tools.

POLICY QUESTIONS

Social and political pressure to address the environmental impacts of livestock production has grown to the point that many US policymakers today are asking what to do, not whether to do something. The setting is one where agricultural policy and environmental policy, which traditionally have separate agendas and priorities, come together on some points. A major direction of inquiry is what strategies will be effective and attainable, who should be responsible for developing and implementing strategies to address known and future problems, and who should bear the burdens of new strategies.

One set of policy questions concerns the role of government in addressing animal waste issues. In the US, federal, state, and local governments currently have numerous programs and policies in place, ranging from regulatory programs for implementing water quality requirements, to programs providing technical assistance and financial incentives to farmers for improved waste management practices. Policymakers debate the appropriate balance of regulatory and incentive-based approaches.

State and local governments implement programs on regulation, siting and zoning, technical assistance, and cost sharing. A key question is what degree of federal leadership and national consistency is appropriate and how federal policies will blend with those of states, regions, and localities.

Further, there are questions about additional aspects of government s role generally in addressing animal waste issues. For example, is there a role for government in facilitating exchange or transfer of manure to lessen imbalances between areas with intense animal production and areas with fewer livestock farms where the nutritive value of manure can be used? Is there need for government to encourage certain manure management practices with potential for increasing the nutrient value while reducing off-site damages?

Experts have identified a number of areas of research needed to inform current and new animal waste management policies in the US and elsewhere. Many believe basic research on manure use and disposal is needed. Other research requirements include improved soil tests to determine nutrient application rates and methods, and improved systems to identify water resources at risk from manure and fertilizers (i.e., those where geology, soils, and climate create potential for runoff and erosion). Two related questions are: who should take the lead on research questions (government or industry, for example), and whether some research must precede implementation (e.g., studies on crop uptake of nutrients and application of phytase or other nutrient-reducing enzymes in feed). Efforts to educate and assist farmers in understanding the value of manure as a soil amendment and the use of alternate disposal techniques are also a priority.

Aquaculture and Environment: Global View from the Tropics to High Latitudes

Malcolm C M Beveridge
University of Stirling, Stirling, Scotland

Aquaculture, the farming of aquatic organisms, is the fastest growing food sector. Over the past 10 years, production by

weight and value has doubled, as has the contribution of farmed aquatic products to world sh and shell sh supplies. One sh in four on our plates is now of farmed origin. Aquaculture has also become an important source of employment, especially in remote, rural areas.

With the rapid expansion of the industry, however, has come growing concern about the impacts of certain types of aquaculture. Much of the recent losses of mangroves in the coastal zone of Asia and Latin America have been attributed to shrimp farming. The more intensive types of aquaculture use considerable quantities of water and are heavily reliant on shmeal- and sh oil-based diets. Copious quantities of dilute, dif cult to treat wastes, sometimes with residues of chemicals used in disease treatment, may be discharged directly into the environment. The movement and escape of farmed aquatic animals is also causing concern in some parts of the world.

Aquaculture is the aquatic counterpart of agriculture, with aspirations to farm all species that might prove of use, including microorganisms, plants, invertebrates, fish, amphibians and reptiles. Farming in the aquatic context may be differentiated from hunting (fishing) because, as in agriculture, some measure of care or cultivation is involved. A further factor distinguishing it from hunting is ownership of stock. The definition currently accepted by the Food and Agriculture Organization (FAO) of the United Nations accepts that both husbandry and ownership are intrinsic, stating that aquaculture is:

> . . . the farming of aquatic organisms including crocodiles, amphibians, finfish, mollusks, crustaceans and plants, where farming refers to their rearing to their juvenile and/or adult phase under captive conditions. Aquaculture also encompasses individual, corporate or state ownership of the organism being reared and harvested . . ..
>
> (Rana *et al.*, 1999)

Note that aquaculture includes organisms owned and reared other than for food for production of food for other farmed aquatic species (microalgae, such as *Isochrysis galbana* and the brine shrimp *Artemia* spp.), leather for clothing and fashion accessories (crocodiles), jewelry (pearls), fine chemicals (the alga *Dunaliella*, for carotenoids), even pets (aquarium species) are considered as products of aquaculture. Despite the attempts at clarification, gray definitional areas remain. For example, the term ranching, generally applied to the release of hatchery-reared organisms into the environment where they mingle with wild stocks of the same species and are in due course harvested together with the wild stocks, using conventional fishing methods, needs further clarification.

The origins of fish and shellfish farming are lost in history, there being few artifacts to guide the historian. Nevertheless, we know that fish and shellfish farming began in a number of parts of the world and at various stages along the aquatic food supply line, between water and plate, several millennia ago. Aquaculture is, almost by definition, an activity of settled societies and originated among both fishing and wetland farming cultures as well as at points of trade. We can surmise that conditions similar to those initiating the development of agriculture would usually have been necessary, that foraging and hunting (i.e., fishing) were insufficient to satisfy demands for fish and shellfish, resulting in some form of stock management being introduced to increase harvestable supplies. It is believed that a range of proto-aquaculture activities, a term coined to describe the various types and degrees of intervention aimed at increasing the biomass of aquatic organisms that could be exploited by humans, paralleling what is now believed to have happened in agriculture (Harris, 1996), were probably practiced. Precursors to aquaculture can still be found, for example, in the early forms of *vallicoltura* (managed lagoons) initiated by the Romans some 2000 years ago. Although perhaps pre-dated by events in Africa, Asia (China in particular) is widely regarded as the cradle of aquaculture. Aquaculture is thought to have evolved here at a comparatively early stage, perhaps as far back as 3000 years ago, among agrarian societies that farmed wetland areas (Bray, 1984). It is believed that Chinese emigrants took various species of carp and the techniques of fish farming with them first to Korea and then to Japan from where the technology gradually spread to other parts of Southeast Asia. The early Christian church, with its emphasis on meatless days and the development of monastic cultures with strong agrarian skills, was a major factor in the development and spread of aquaculture in Western Europe.

Despite its ancient origins, aquaculture is a largely post-second world war phenomenon. In 1950, global farmed fish and shellfish production was around two million tons (Figure 1) and largely confined to areas of Asia. Why? Most obviously, there was little need to farm fish and

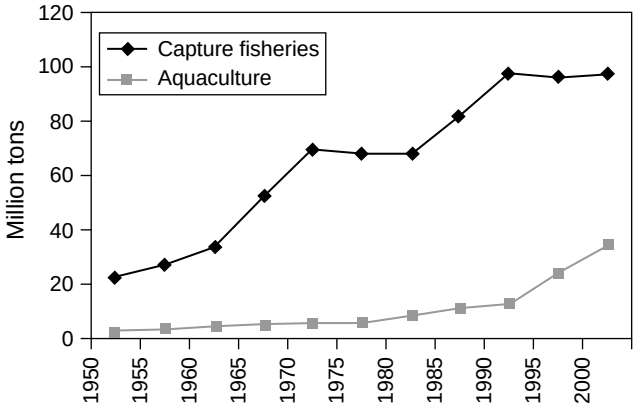

Figure 1 Growth in global fisheries and aquaculture production, 1950–1997. (Based on FAO data)

shellfish for food. Supplies were plentiful, even in the middle years of the present century. The Second World War had curtailed fishing activities and allowed stocks to recover. Growing demand and the development of increasingly effective means of finding and exploiting fish, however, quickly undid the good that the hiatus in fishing had produced, leading to increasing numbers of stocks becoming over exploited. Degradation of aquatic environments through pollution and impoundment of rivers further exacerbated the situation, while the burgeoning global population, combined with urbanization and rapid economic growth stimulated demand.

Over the past half century, aquaculture production has grown nearly 20 fold to 36 million tons in 1997, comprising 16.7 million tons of finfish (49% of the total), 8.5 million tons of mollusks (25%) and 7.7 million tons of aquatic plants (23%) (FAO, 1999). The increasing rate of growth of aquaculture production has resulted in a more than doubling of the contribution to total world fisheries production (capture and culture) from 11% in 1984 to 26% in 1997. Much of the growth has been in farmed freshwater fish production in China where it proved possible to address the demands for fish from the rapidly growing population through universal collectivization of land and other resources, the development of a rigorously planned agricultural system and wide-scale impoundment of rivers. The significance of farmed aquatic organisms is even greater than production statistics indicate. At US$50.4 billion, farmed aquatic products account for half the value of global capture and culture fisheries production. From a human food perspective, more than 25% of fish eaten (one fish in four) comes from aquaculture. There are, however, tremendous regional differences in production (Figure 2). More than 90% occurs in Asia, China alone accounting for more than two thirds of the total. By contrast, Europe and America account for less than 5% and 2% of aquaculture production, respectively. While nearly 90% of aquaculture production is from developing countries and 82% is from low income food deficit countries (LIFDCs) (Tacon, 1998), production in Africa (120 000 tons; 0.3%) remains trivial, especially in relation to the problems that the continent faces in feeding its population.

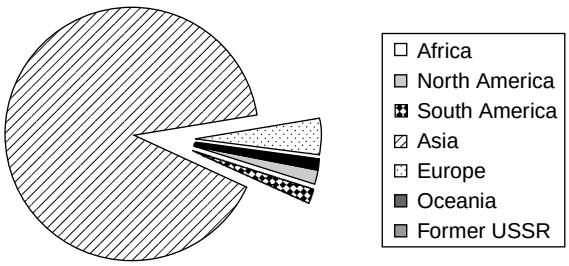

Figure 2 Regional differences (%) in global aquaculture production in 1997. (*Source:* FAO (1999))

Aquaculture remains primarily about rearing fish and shellfish for food; and growth has been largely market-driven. Production of low value species, especially that of carps, has increased tremendously in Asia. However, production methods are intensifying, largely because of increasing pressure on land and water resources (Beveridge *et al.*, 1997a). Growth in incomes in many Asian newly industrialized countries has also fuelled demand for luxury foods, such as live farmed grouper (*Epinephilus* spp.) and seabass (*Lates calcarifer*). Export markets in Japan, Europe and North America for high value farmed aquatic products such as shrimp are strong. The spectacular returns on investment in shrimp farming attracted many investors both in Latin America and in Asia while the implications for foreign exchange arguably influenced the lax environmental regulatory policies of governments. Only in the 1990s have disease and the deleterious effect on mangrove and other coastal resources constrained growth. In Europe, fastest growth has been seen in the production of high market value fish species such as Atlantic salmon (*Salmo salar*) and gilthead seabream (*Sparus aurata*). Throughout the 1990s falling consumer prices have driven the expansion of the market and alternative species/products are now urgently needed. Technical constraints, however, especially with regard to the spawning and larval rearing of marine fish and crustaceans, and production economics have somewhat tempered development.

Aquaculture usually involves maintaining a species in a secure facility under conditions in which it can thrive. Interventions in the life cycle, or husbandry practices, range from exclusion of predators and control of competitors (extensive) through enhancement of food supply (semi-intensive) or even, in intensive aquaculture, the provision of all nutritional requirements. While control over all aspects of an organism s life cycle is desirable, enabling selective breeding for desirable traits such as improved growth, disease resistance or flesh quality, lack of knowledge and economics has constrained reproduction and larval rearing in captivity of many (especially marine) species. Two types of aquaculture system prevail: water-based and land-based. The former includes cages and pens for fish and trestles and long-lines for mollusks while the latter comprise ponds, tanks and raceways used in fish rearing. Mollusks, including species reared for pearl cultivation, are generally farmed in inter-tidal and sheltered inshore coastal areas, where wild caught or hatchery-reared seed (larvae/post-larvae) are typically grown in bags set on trestles or lantern nets or ropes suspended from the water surface. The animals are entirely reliant on prevailing supplies of plankton for food. Crustacean farming is dominated by that of penaeid shrimp in countries such as Thailand, Ecuador, China and Indonesia. Shrimp post-larvae, derived either from wild fisheries or from wild-caught egg-bearing females, are stocked in coastal ponds and

grown for 3 4 months until they reach marketable size. The more intensively managed shrimp farms are heavily reliant on pelleted, nutritionally complete feeds and use pumped seawater to replenish dissolved oxygen and flush away potentially harmful waste metabolites. A range of systems, ponds, tanks or cages is used to farm fish. Ponds predominate in the tropics and sub-tropics to semi-intensively rear carps and other freshwater species, usually in an agricultural setting. By contrast, much culture of marine fish in coastal areas is in floating net cages where intensive rearing methods, involving the use of nutritionally complete fishmeal and fish oil-based diets, are employed (Figure 3).

Aquaculture is reliant on a wide range of natural resources or environmental goods, including:

- land (or space in the sea) in which to site an aquaculture facility;
- materials (timber, steel, etc.) for construction of the system and ancillary facilities (roads, offices, etc.);
- water to support the animals;
- seed (eggs, larvae, past-larvae, fry) for stocking;
- feed and/or fertilizers to enhance production.

Figure 3 Plastic seabass and seabream cages, Mediterranean Spain. This technology is widely used for marine fish culture in northern Europe and is rapidly being adopted in Southeast Asia

Because production is carried out in ecologically open systems, in which materials are imported to the production site and transformed into marketable products through inputs of energy, wastes are inevitably produced. Wastes include:

- uneaten food, fecal and urinary products;
- drugs and chemicals used to combat disease (chemotherapeutants);
- feral (escaped) animals and pathogens that find their way into the environment.

Aquaculture is also dependent upon the environment for essential services: the replenishment of oxygen and the dispersal and assimilation of wastes that otherwise might accumulate in the production system, exerting negative feedback on farmed animal growth and production (see Figure 4). Thus, factors that determine the supply of environmental goods and services, such as changes in land use and pollution, may adversely affect aquaculture. Impacts of aquaculture on the environment stem from the consumption of environmental goods, from the transformation (i.e., farming) process itself and from the production and release of wastes. The overall relationship ranges from the positive (i.e., enhancement of environmental quality) through the relatively neutral, to that which results in environmental degradation. In general, the higher the demand for environmental goods and services, the greater the impacts on the environment.

In the public s mind, much of the controversy surrounding aquaculture revolves around the issue of the impact of aquaculture development on the landscape. While few

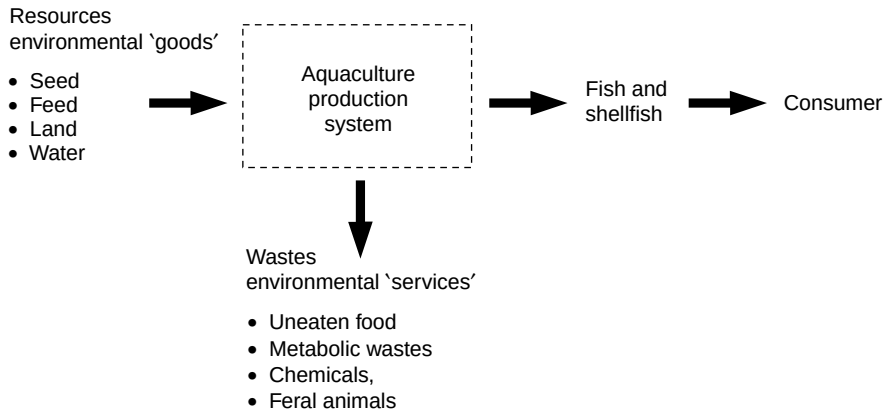

Figure 4 Interactions between aquaculture and the environment, illustrating its dependence on environmental goods and services (modified from Beveridge *et al.*, 1997b)

would claim that aquaculture developments enhance the landscape, there are marked differences among countries and social groups in response. Such issues have led to zoning of developments in areas such as Hong Kong (Beveridge, 1996).

Inland aquaculture is usually located in agricultural land and here the development of ponds can increase habitat diversity (Beveridge and Phillips, 1993). By contrast, tropical marine shrimp and fish culture usually utilizes previously unexploited areas for ponds. Demands for land for shrimp pond construction in Latin America (Ecuador, Colombia) and Southeast Asia (China, Thailand, Indonesia, and the Philippines) have caused the destruction of thousands of hectares of mangrove. Some 65 000 ha of mangrove in Thailand and 100 000 ha in Vietnam, for example, are believed to have been converted into shrimp ponds in recent decades (Primavera, 1998). As a result of seepage, areas of land adjacent to seawater ponds are also often subject to salinization, adversely affecting agricultural activities (Phillips *et al.*, 1993; Primavera, 1998). The removal of mangroves not only represents the loss of a unique habitat type, but it also reduces the availability of food, fuel and building materials for the poorer sectors of coastal communities. Through its role as a nursery habitat for commercially important offshore species and as an important intermediary governing the flow of nutrients and soil from the land to the sea, the loss of mangroves adversely affects coral reefs and offshore fisheries.

Aquaculture uses large quantities of water, use being determined by species and the intensity of the operation. Estimates of water used in semi-intensive and intensive shrimp culture, for example, are around 11 000 21 000 $m^3\,t^{-1}$ and 29 000 43 000 $m^3\,t^{-1}$, respectively (Phillips *et al.*, 1993); requirements for salmonids are typically even higher. Losses from ponds through seepage and evaporation can amount to several hundred cubic meters of water per hectare pond area per day. However, although it often makes greater economic sense to use water for purposes other than aquaculture where it is in short supply, a fish pond on a family farm can also improve water conservation and use.

Most farmed freshwater species are reared in captivity throughout their life cycle. This is desirable from the farmer s point of view since it facilitates selection for economically important traits and is a prerequisite in the manipulation of sex and in the production of year-round supplies of seed. By contrast, marine fish and shrimp culture is still largely dependent upon the supply of seed (eggs, larvae, fry, juveniles or, in the case of shrimp, gravid females) from the wild. Mollusk farming uses both wild-caught and hatchery-reared seed, depending on species and circumstances, but this is unlikely to have much impact on the environment. While undoubtedly there remain many technical barriers to breeding, the economics of production also often do not justify the development of commercial marine fish and shrimp hatcheries. Although the wastage associated with collecting shrimp post-larvae and milkfish fry is widely recognized as tremendous, the vast proportion of material caught being discarded as by-catch (Beveridge *et al.*, 1997a,b; Primavera, 1998), impacts on stocks and on biodiversity are difficult to evaluate given that most stocks exploited in this way are also subject to over-fishing.

Much fish and shrimp culture is dependent upon the provision of trash fish or fishmeal and fish oil-based feeds. It takes four tons of wild fish (mainly anchovies and sardines) to produce one ton of fishmeal. In 1997, some 2.3 million tons of fishmeal and 670 thousand tons of fish oil, about one third of world supplies, were used in aquaculture feeds. Although farming of carnivorous fish such as salmon results in a net loss of fish, Naylor *et al.* (2000) estimate that the production of the 10 most important farmed aquatic species is approximately 1.8 times greater than the quantities of marine fish used in their production. It is also argued that industrially harvested species are fit for no other purpose than reduction to fishmeal.

Irrespective of production method, the establishment of an aquaculture operation can impact on both scenic value and biodiversity. Cage or mussel farming structures act as feed attractant devices (FADs) or substrates for other species while the stocks of fish, shellfish and feed may attract predatory or scavenging fish, birds and mammals (Beveridge *et al.*, 1997b). Immigrants may impose increased predation pressure on wild fish populations in the vicinity of the farm or compete with and displace resident breeding populations, as has been claimed with regard to bird populations in areas in Scotland. Losses of farmed stock to predators can be economically significant and the measures used as deterrents often lead to death, either deliberate (shooting) or accidental (entanglement). Increased levels of activity around farms in isolated areas may disrupt species sensitive to the presence of humans and noise.

Feed losses vary with species and system. Due to currents, losses from marine cages, typically 5 10% of food fed, are generally higher than from other systems. Faecal production from fish and crustaceans is around 230 400 $g\,kg^{-1}$ food ingested. In ponds, much of the solid material remains trapped until harvesting. However, in cages, uneaten food and faecal material continuously falls through the nets towards the sea bottom. As it does so, it tends to break up, increasing the leaching of nutrients into the water column and the area of seabed over which the solids disperse. The major source of dissolved nitrogenous waste, however, is excretory products. Depending on species, dietary protein content and environmental conditions, urinary nitrogen can account for up to 60% of nitrogen released into the environment by intensive fish production (Beveridge *et al.*, 1991).

Fish and shrimp farm effluents and their impacts have been well studied. While hypernutrification, eutrophication

and oxygen depletion of the water column around cage farms is sometimes apparent, given the degree of water movement at most coastal sites, effects are generally only apparent during periods of slack tide. Impacts on the seabed, especially around cage sites, are more readily observable. Loss in sediment habitat heterogeneity is apparent, the area under or immediately downstream of the cages being most affected. Sediments here are largely devoid of oxygen, are highly reducing, and may be devoid of macrobenthos. The anaerobe *Beggiotoa* is often apparent on sediment surfaces. Some 10 20 m distant from the cages, pollution tolerant macrobenthic species such as *Capitella* are found in high numbers. There is usually a return to undisturbed community structure and function within 100 150 m (*see* Aquaculture: Salmon Farming, Volume 3).

Although farmed mussels and other filter feeding mollusks are net removers of nutrients, rafts and long-lines increase rates of biodeposition in the immediate vicinity, reducing biodiversity within the benthic macroinvertebrate community.

A wide range of chemicals is used by the mariculture industry, including compounds found in construction materials (stabilizers, pigments, plasticisers, ultraviolet (UV) absorbents, antifoulants), pigments incorporated into feeds, and chemotherapeutants. There is particular concern about chemotherapeutants because of the amounts used, the ease with which they enter the environment and the lack of knowledge of their effects. Approximately 30 antibacterial compounds are used in aquaculture (Weston, 1996), use being determined by farmed species, pathogens, farm location and intensity of production methods. Greatest use is in marine finfish farms in Europe, Japan and North America and Asian and Latin American shrimp ponds. The quantities used can be enormous. Norway has kept records of antibacterial use by fish farmers for more than a decade (Beveridge *et al.*, 1997b). Quantities used peaked at 49 tons in 1987, but have since declined to only a few hundred kilos per year through the development of vaccines and better disease management.

The bulk of aquaculture production is from a few dozen species, many of which have been translocated. The Pacific cupped oyster *Crassostrea gigas*, for example, is farmed throughout much of the world, far outside its natural range. Aquaculture, however, remains a comparatively minor factor in relation to other causes of species introduction, both deliberate (fisheries development) and accidental (construction of canals, ballast water transport, etc.) (Beveridge *et al.*, 1997b).

The transfer of exotic aquatic organisms poses two threats to biodiversity, from the organism itself and from associated pathogens. Viral pathogens of shrimp and salmon and protozoan parasites of mollusks have been translocated in this way. Farmed organisms will always escape, cages being particularly vulnerable. Escapes occur on a small but almost continuous scale during day to day management of stock (grading, stock movements). Nevertheless, numbers lost in this way may greatly exceed those of neighboring wild populations. Moreover, storm damage or vandalism can result in the periodic releases of many thousands of animals. The fear is that feral organisms become established and reduce biodiversity through habitat modification, competition and predation and by inter-breeding with native stocks (Gross, 1998). Many feral species have become established in freshwaters (Welcomme, 1988). While there is little evidence that exotic feral farmed marine organisms have become established (Beveridge *et al.*, 1997b) or that serious impacts on the environment or on biodiversity have resulted, there has also been little study of the fate of such organisms. In Chile, for example, there is no information on the impacts of the many hundreds of thousands of farmed salmonids that undoubtedly escape each year.

The farming of native species reduces risks of habitat modification and interspecific interactions but may introduce non-adaptive traits (gene combinations) to indigenous stocks, reducing fitness and endangering populations. Farming of local strains may not always be a solution. Native animals brought into the hatchery pass through various selection bottlenecks, either accidental (disease) or deliberate (selection for growth, shape, colour), and within a few generations differ from their wild ancestor (*see* Aquaculture: Salmon Farming, Volume 3).

DISCUSSION

Aquaculture is an increasingly important means of producing aquatic food. It is also apparent that the increases in production and the trend towards intensification are not without cost. There has been insufficient analysis to determine the real contribution of aquaculture to global food supplies or to assess whether it is a more or a less efficient means of producing food than agriculture. However, the more intensive types of aquaculture undoubtedly result in a net loss of fish or protein and despite efforts to find substitutes, demand for fishmeal and fish oil by the aquaculture industry is likely to remain largely unchanged for some time. Aquaculture wastes are characteristically dilute in nature and are difficult and costly to treat and there remain intractable disease problems, treatable only with noxious chemicals. Waste discharges into the environment can cause localized impacts, although their significance at the regional scale is contentious.

Many of the environmental problems have undoubtedly been due to ignorance; after all, modern aquaculture is only a few decades old. Lessons have been learned. Recent European Directives, for example, have led to empowerment of regulatory authorities to demand that environmental impact assessments (EIA) of proposals to site particular types of

aquaculture development in sensitive areas in Ireland, Scotland, Spain and Italy be carried out. Greater control of fish farm effluents, and thus expansion of production, has resulted from reclassification of Scottish salmon marine farms as industrial sites and the necessity to obtain consents to discharge. The rate of destruction of mangroves for aquaculture also seems to be waning. Legislative measures to protect forests are being implemented at last. Areas in Vietnam and Thailand are being replanted and more integrated aquaculture mangrove management projects encouraged. Wastes per unit production have been decreasing in many sectors through a combination of production economics, increased public scrutiny of farming methods and the influence of producer organizations, such as the Scottish Quality Salmon. Initiatives, such as the Global Biodiversity Convention, have led to the development of the Code of Conduct for Responsible Fisheries that includes guidelines pertaining to aquaculture (FAO, 1997). These are increasingly being considered in the regulation of the industry. The consumer too has recently entered the debate, and that more than anything is likely to further improve farming methods.

Aquaculture in Asia

Fumio Takashima

Tokyo University Fisheries, Tokyo, Japan

The annual global production by traditional sheries was around 93 million metric tonnes in 1997, whereas aquaculture production in the same year was 36 million tonnes. In many parts of the world, and especially in Asia, aquaculture is becoming a major industry. Asian aquaculture production has been increasing year by year and attained 32.5 million tonnes (about 90% of the world's production) in 1997. About half of it was produced in freshwater and the other half in coastal areas. The main freshwater species produced by aquaculture in Asia are the carps (common carp, Chinese carps and Indian carp), tilapia, eel and cat sh in warm water, and rainbow trout and coho salmon in cold water. Marine species such as yellowtail, seabream, ounder, grouper, milk sh and mullet are important species in many countries. Certain species of shell sh such as tiger shrimp, oyster, clam and abalone are also widely cultured. Among the sea algae, laver, Japanese kelp and wakame are the main species in some countries (Japan, Korea and

China) whereas agar- agar predominates in others (especially Southeast Asian countries).

HISTORY

The common carp originated in Central Asia and was transported into Europe, China and West Java more than 3000 years ago. The technical textbook on carp culture written by Fun Li in China in BC 500 indicates that aquacultural techniques were already developed in ancient times. Milkfish culture in Indonesia also has a long history, fry for culture having been collected along the beaches in Java for more than several hundred years. Rainbow trout, first introduced from North America nearly 100 years ago, is now widely distributed wherever cold water is available. Tilapia was introduced from the Nile River via the Middle East and is now common in Asian countries where warm water is abundant. Culture techniques of eel and tiger shrimp were developed after the Second World War in Asian countries. Several native species can now be cultivated in some countries thanks to the efforts of local researchers and technicians.

According to the Food and Agriculture Organization s 1997 statistics, China is the leading country in aquaculture production with about 24 million tonnes, and Japan was second with about 1.3 million tonnes. In addition, Korea (1 million tonnes), Philippines (958 000 tonnes), Indonesia (912 000 tonnes), Thailand (576 000 tonnes) and Taiwan (270 000 tonnes) produced abundant fish, shellfish and sea-algae.

COMMON CULTURING TECHNIQUES

The aquaculture systems in Asia may be classified in terms of their efficiency of cultivation into three groups: extensive, semi-intensive and intensive aquaculture. The systems may be further classified by means of the type of installation (pond, cage, partition or raft) and of water movement (stagnant, running or circulating water). In some cases, the rearing systems are divided into feeding or non-feeding conditions.

AQUACULTURE IN ASIAN COUNTRIES

China

China not only has one of the largest freshwater and coastal areas in the world, but also the longest history in raising fish. China has developed intensive and integrated polyculture systems that are cost-effective, highly productive and less dependent than the fishing industry on energy sources and modern technology. The achievements of Chinese aquaculture have made China the largest producer of cultured fish in the world. The major approaches for the development of aquaculture in China are: polyculture systems, integrated fish farming systems, artificial propagation of cultivated fish and large-scale production of fish seeds, expansion of culture areas and enhancement of productivity, and strengthening of the prophylaxis and therapeutics of diseases. China produced 24 million tonnes of fish, shellfish and algae in 1997. In this country, extensive culture in warm fresh water is predominant in stagnant ponds, reservoirs and paddy fields. Common carp (*Cyprinus carpio*) and Chinese carps such as grass carp (*Ctenopharyngodon idellus*), silver carp (*Hypophthalmichthys molitrix*), bighead carp (*Aristichtys nobilis*) and black carp (*Mylopharyngodon piceus*) are the dominant species, comprising a production of about 9 million tonnes (74% of all freshwater species). Polyculture is the main method of freshwater aquaculture and has a long history in China. Mixed culture of the four major Chinese carps has been practiced since as early as the end of the Tang Dynasty, about 1000 years ago. The major advantages of polyculture are the efficient use of the space and food available in the pond, the increase in the utilization rate of artificial feeds, and the maximization of the beneficial interactions between compatible species with different habits and ecology. The integrated fish farm is another system of non-feeding aquaculture for omnivorous and herbivorous fish such as common carp and some of the Chinese carps. This system raises livestock such as pigs, ducks or poultry and uses their manure for increasing the abundance of natural food organisms (plankton). The same system is also employed in Southeast Asian countries such as India and Indonesia.

Indonesia

Aquaculture in Indonesia is mainly practiced in fresh and brackish water. The total freshwater fish production in 1997 was 357 000 tonnes, with paddy fields and net cages contributing almost 90% of the production. Freshwater cultivation is also done in stagnant and running water ponds and in bamboo cages in rivers. The rice paddy and net cage cultures are related, in that the farmers rear fish fry up to young (100 g) in the former, and from young to marketable size in the latter. Net cage culture is well developed in some reservoirs in West Java but it is not so common in other areas. Common carp is the dominant species cultured in reservoirs and paddy fields. Tilapias (*Oreochromis niloticus* and *Oreochromis mossambicus*), giant gouramy (*Osphronemus goramy*), Java barb (*Puntius javanicus*) and catfish (*Clarias* spp.) are also important cultured species. The numerous net cages in some reservoirs cause great accumulation of organic waste at the bottom. The suspension of this waste during the rainy season, due to massive water inflow from rivers and convection currents created by temperature changes, causes a sudden decrease of dissolved oxygen and provokes the suffocation of fish. Brackish water aquaculture produced 398 000 tonnes in 1997. The cultures of the

main species, milkfish (*Chanos chanos*, 168 000 tonnes) and tiger shrimp (*Penaeus monodon*, 100 000 tonnes), have a long history and are widespread in Indonesia. Shrimp and milkfish farming is developed in ponds (tambak) built in coastal areas after taking off the mangrove trees. A part of the mangrove tree is sometimes left in the pond to help preserve the environment and this system is known as *tumpangsari*. Tumpangsari use is gradually spreading to other countries. In addition, the biocrete system of shrimp farming ponds has been developed along the southern coast of West Java, in order to avoid the spreading of serious diseases such as that evoked by Monodon baculovirus. In this system, the bottom of the pond is covered with a plastic sheet and the dyke is also covered with a mixture of bamboo, palm fiber, sand and cement. Coupled with technologies such as formulated feed, water quality management, selective breeding, disease control and hatchery techniques, shrimp culture in Indonesia (and also in other countries) has become more efficient, producing more shrimp in less culture area. Farmers gradually have come to realize that intensive shrimp culture must be sustainable and that mangrove destruction for construction of shrimp ponds should be gradually reduced. In the coastal areas of Indonesia, without muddy outflow from rivers, sea-algae for agar agar (Rhodophyceae) is propagated and harvested (157 000 tonnes).

Japan

Most Japanese aquaculture is highly intensive and uses advanced equipment such as net-cages, partitions, raceway ponds and recirculation ponds. Net-cages are square or round in shape and usually consist of a steel frame surrounded by a net. Net-cages are used for yellowtail (*Seriola quinqueradiata*), red seabream (*Pagrus major*), coho salmon (*Oncorhynchus kisutch*) and common carp whereas partitions by net are used for yellowtail and kuruma shrimp (*Penaeus japonicus*). Raceway ponds are common for salmonids. Water recirculation systems are used for eel (*Anguilla japonica*), ayu smelt (*Plecoglossus altivelis*) (freshwater) and olive flounder (*Paralichthys olivaceus*). The stocking density in each system is different depending on the species, the volume of water contained and the exchange rate of the water, which affects the supply of dissolved oxygen. Releasing the juvenile or fry into open waters is called sea farming, and this technique is now quite developed for salmon (*Oncorhynchus* spp.), red seabream, kuruma shrimp, abalone (*Haliotis* spp.), swimming crab (*Portunus trituberculatus*) and ayu smelt. Suspension of shells with spats of oysters (*Crassostrea gigas*) in the sea is a unique method originated in Japan about 100 years ago. This technique was adopted for scallop (*Patinopecten yessoensis*), pearl oyster (*Pinctada* spp.) and sea squirt (*Halocynthia roretzi*) with the modification that juveniles or young are suspended under water inside net bags. Floating nets with spores of laver (*Porphyra ezoensis*) or wakame (*Undaria* spp.) have been recently developed and have started to yield considerable amounts of these species of edible algae. In most cases of finfish and kuruma shrimp farming, artificial food made of fish and vegetable meal and supplements including minerals and vitamins are used. Disease is the most serious problem in the case of highly intensive culture systems and this problem has been tackled with drugs and vaccination programs sanctioned by the government. Genetic control of disease is also being pursued through the experimental introduction of resistant genes into the animals. Studies are now in progress to adapt the *hazard analysis critical control point* (HACCP) concept to aquaculture, and in the near future fish farm products will be required to be HACCP-compliant. This system is a systematic approach to assure the safety of foods that focuses on prevention (early identification of potential biological, physical or chemical hazards to human health, control, and monitoring) rather than remediation of problems. Some of the main species in 1997 were yellowtail (138 000 tonnes), red seabream, (81 000 tonnes), laver (393 000 tonnes), wakame (70 000 tonnes), kelp (60 000 tonnes), scallop (254 000 tonnes), oyster (218 000 tonnes), common carp (12 000 tonnes) and rainbow trout (*Oncorhynchus mykiss*, 13 000 tonnes), among others.

Korea

The Korean aquaculture industry grew rapidly from 1960 until the late 1980s. During this initial stage of development, non-feeding aquaculture species such as common carp and crucian carp (*Carassius auratus*) represented the bulk of the production. Recently, marine finfish, such as olive flounder and red seabream, are farmed under the feeding system and represent nearly 90% of the total production of farmed marine fish. In addition, the production of shellfish such as oyster (201 000 tonnes) and sea-algae (wakame, laver and kelp, 613 000 tonnes) has recently increased. Rainbow trout, Japanese eel, ayu smelt, tilapia and catfish (*Ictalurus punctatus*) have been introduced from abroad, and reared in various parts of the country. The continued growth of the aquaculture industry in Korea is gradually being constrained by deterioration in the quality of water resources, caused by urban and industrial activities as well as aquaculture itself, and market competition within the country.

Philippines

In 1997, the production from aquaculture reached a total of 958 000 tonnes, of which 65% was from seaweeds, 27% from fin fish, 5% from crustaceans and 3% from shellfish.

Milkfish is the most important finfish for aquaculture in the Philippines. Farming of milkfish has gradually shifted from the extensive method to semi-intensive and intensive methods. Cage culture of milkfish, tilapia and other commercially important species is found both in the sea and in fresh water (lakes and rivers). High stocking-density farming in pens and cages is now common. Tiger shrimp farming increased sharply from 1992 1994 but dropped thereafter. Due to the commercial importance of mud-crab (*Scylla* spp.), the aquaculture of this species is now increasing and production reached about 4000 tonnes in 1997. The production of tilapia developed greatly in the last 10 years and is currently about 92 000 tonnes, making the Philippines one of the world s leading producers of tilapia. Genetically developed hybrids of tilapia such as monosex individuals or YY-male are fast gaining consumer acceptance and are being rapidly distributed among the producers. The major commodities produced in mariculture are the seaweeds *Eucheuma* spp. and *Caulerpa* spp., oysters (*Crassostrea* spp.), and mussels (*Mytilus* spp.). In 1997, seaweed production totaled 627 000 tonnes, that of oysters 14 000 tonnes, and that of mussels 12 000 tonnes.

Thailand

Aquaculture techniques in Thailand are fairly advanced, particularly concerning seed production, where the application of techniques for induced spawning has become popular. In 1997, the total production from aquaculture was 576 000 tonnes including the products from fresh water (265 000 tonnes), brackish water (222 000 tonnes), and marine water (89 000 tonnes). Freshwater culture is practiced in four main types of installations, namely paddy fields, ditches, and cages in ponds or lakes. The major species in pond culture are the tilapias, gouramy (*Trichogaster pectoralis*), catfishes (*Clarias gariepinus* and *C. macrocephalus* hybrids, *Pangasius pangasius*), and silver barb (*Puntius gonionotus*). Tilapia has a particularly good potential for future development. Brackish water culture is practiced in the coastal area and concentrates on tiger shrimp culture.

Thailand has the highest shrimp production of the Asian countries (Table 1). Shrimp culture systems in Thailand have three levels of intensity: extensive, semi-intensive, and intensive. Extensive culture systems are characterized by low stocking densities and, therefore, lesser productivity. This system is characteristic of coastal communities with little income. Semi-intensive culture ponds may be created through the intensification of existing extensive ponds. This may include improvements such as clearing, leveling and/or digging canals in the pond bottom, converting from the mere use of tides to the intensive use of pumps for water exchange; controlling stocking density, greater use of fish toxicants to control nuisance species, and provision of feeding. The intensive system for shrimp farming is very similar to the Taiwanese system. The adoption of new technologies allowed a reduction in the production time to four months per crop and raised the production rate to 6000 10 000 kg ha^{-1} $year^{-1}$. Intensive farms do not harvest wild juveniles but rely on the large numbers of fry produced in hatcheries. Due to the high stocking density and the use of supplement feeding, there is a large organic accumulation at the pond bottom after a period of culture. This requires complete drying between successive cultures to facilitate removal of waste and sanitation. The brackish water culture, especially that of shrimp, apparently has reached the maximum sustainable yield. The main species for mariculture in Thailand are shellfish such as blood cockle (*Anadara granosa*), mussel (*Mytilus smaragdinus*) and oysters (*Crassostrea* spp.). There is a great demand for these shellfish in the domestic market.

Table 1 Tiger shrimp production in Asia in 1997

Countries	Production (metric tonne)
Thailand	211 100
Indonesia	99 680
Vietnam	60 000
India	54 483
Philippines	40 102
Malaysia	9380
Taiwan	5161

Taiwan

Aquaculture in Taiwan has a history of more than 300 years and has expanded rapidly in recent times due to factors such as the vast and ever-increasing demand for seafood, highly skilled and motivated aqua-farmers, excellent support from research and extension services and thoroughly integrated peripheral industries and side-business. The high diversity and availability of cultured species (around 200 species are presently cultured) also attest to the significance of the Taiwanese aquaculture industry. The total production in 1997 was 270 000 tonnes. The major species cultured in Taiwan are finfish such as Japanese eel (22 000 tonnes), milkfish (31 000 tonnes) and tilapia (42 000 tonnes). Eel farming is typically an intensive industry with great importance in Taiwan, ranking top in aquaculture in terms of value and quantity of production. Eel ranks top also among exports of agricultural products and most of it is exported to Japan. Milkfish culture was developed in Taiwan about 300 years ago. In general, the management methods of milkfish culture can be divided into the traditional shallow-water culture and the modern deep-water pond culture systems. The former method is based on enhancing the production of benthic algae as food for milkfish by administration of organic fertilizer to shallow (30 40 cm) brackish or saline water

ponds. It is practiced extensively: no feeding, no aeration, with low stocking density and as a result of this, the maximum yield is around 2–2.5 tonnes ha^{-1}. The latter method is based on farming the fish in deep (2–3 m) brackish or fresh water ponds. It is practiced intensively, with the use of automatic feeding with pellet feeds, aeration, high stocking density, and usually produces maximum yields around 8–12 tonnes ha^{-1}.

Tilapia has now become not only the most common food fish in Taiwan but also an export commodity, with the main destination being Japan. Prior to shipment, fish are acclimatized in seawater to eliminate any parasites and the odor of mud that may impregnate the fish in fresh water. Fish are then filleted, vacuum-packed, and frozen. The species of tilapia most intensively cultured are *Oreochromis niloticus* and its red variety. They are mainly polycultured as the primary crop along with carp or eel, or integrated-cultured as a side-product of the production of hog or duck. Tiger shrimp culture developed rapidly in Taiwan up to 1987. However, the production has been decreasing since 1988 because of the outbreak of diseases such as Monodon baculovirus and those caused by bacteria or protozoa. Complicating factors are the absence of disease control techniques, deterioration of pond environment, overstocking, and the use of poor quality fry. As a result of these unfavorable conditions, the production of shrimp was only 5000 tonnes in 1997, while at its maximum in 1987 it was 79 000 tonnes. Taiwan experienced many of the typical problems posed by a rapidly growing agricultural activity such as the improper utilization of limited land and water resources, environment deterioration, disease outbreaks, and poor coordination between production and consumption.

IMPORTANCE OF AQUACULTURE IN THE 21ST CENTURY AND ENVIRONMENTAL ISSUES

Aquaculture has expanded rapidly since 1960 in Asian countries and now provides as much fish and shellfish as freshwater fisheries in the region. It accounts for about one-fifth of the total fish and shellfish production. Aquaculture is expected to make up the difference between the demand for fishery products and the output from conventional fisheries, which already show signs of stagnation or even decrease. Its importance as a source of animal protein in Asia cannot be underestimated in view of the increase in the region's population predicted for the first half of 21st century.

In order to meet these expectations and expand any further, however, Asian aquaculture will have to address the concerns of the consumers regarding the safety of the product and of society as a whole regarding environmental protection. The introduction of exotic species and the use of genetically modified organisms, although justifiable from a production efficiency viewpoint, deserve careful examination. The adoption of the HACCP concept, as explained previously, and the use of biologically reasonable culture practices (e.g., adequate size of facilities, rearing density, supplemental food, etc.) that help prevent the outbreak and spreading of diseases should help allay fears of contamination of the food with any hazards, biological or chemical. These culture practices should also help mitigate environmental problems caused by aquaculture. For example, aquatic farming in coastal areas, especially of shrimp, has driven much of the transformation of mangrove forests in the region and in some areas, such as Thailand, has nearly reached the point above which further expansion would be unsustainable (*see* **Aquaculture and Environment: Global View from the Tropics to High Latitudes**, Volume 3). Culture systems that minimize environmental impacts in mangrove areas, such as the tumpangsari described previously, should be encouraged and the planning of new farms should take in consideration the need for intervening, buffering natural areas.

The expansion of industrial and urban activity, including reclaiming of coastal areas and resort development, is progressively taking away potential sites for aquaculture. Aquaculture also competes with those activities for water, with conflicts arising due to shortage or deterioration in water quality. However, aquaculture is not only a victim, but also a cause of water pollution. In recent years, pollution through excessive feeding has become a serious problem in the effluents of aquaculture farms, which are carried to open waters, or around culture pens. The use of chemicals for the control of algae in ponds is also a potential source of contamination of surface and ground waters. Thus, aquaculture development must deal properly with the potential impacts of organic and inorganic wastes. Many of the above problems might be mitigated by future developments in the field of closed-circulation culture systems that minimize water intake and permit complete control of liquid and solid wastes.

Aquaculture: Salmon Farming

Trevor C Telfer and Malcolm C M Beveridge
Institute of Aquaculture, Stirling, UK

Although the farming of salmon in sea cages began little more than 30 years ago, it has since grown into a multi-billion dollar industry, employing many thousands of people

in rural areas of western Europe, North America and Chile. Farmed salmon is highly nutritious and is now one of the cheapest shes available to western consumers. Despite this, salmon farming has attracted criticism on account of its reliance on shmeal and sh oil-based diets and the impact of the wastes released into the marine environment.

INTRODUCTION

The seven species of salmon (Family Salmonidae) are all indigenous to the Northern Hemisphere (Table 1). For centuries, salmon have been an integral component of the economic, cultural and religious life of the peoples inhabiting the Northwest Pacific coast of America. In Europe, too, the salmon was of considerable economic importance, exploitation often being regulated by legislation. Many stocks of both Atlantic and Pacific salmon, however, are now sadly depleted.

While it is believed that native North Americans may have attempted to manage stocks by transplanting fertilized eggs, salmon farming has its origins in the early 19th century and was precipitated by factors other than farming. In Europe, the rise of leisure among the upper middle classes, combined with the Victorian drive to improve upon nature, led to salmon being successfully spawned in Scotland in the 1830s and subsequently, salmon hatcheries being built on a number of rivers to enhance recreational fisheries (Williamson and Beveridge, 1994). By the beginning of the present century, however, many of the hatcheries had been abandoned due to expense and questionable returns of stocked fish. In Pacific North America, salmon aquaculture was promulgated in the late 1870s in response to concerns about over-fishing, although they were often unable to remedy the deleterious effects of logging and mill and dam construction (NRC, 1996). Salmon farming to produce food for the table, however, only began in the 1960s in Norway but was swiftly followed by developments in Scotland and Ireland. Salmon farming has since spread to more than a dozen countries, including Canada and the United States and even as far as Chile and Australia in the Southern Hemisphere (see Figure 1). Farmed salmon production now approximates that from *capture* (conventional) fisheries, although production of farmed Atlantic salmon, which accounts for nearly 90% of farmed salmon production, has long outstripped capture fisheries production. Salmon farming, however, has done little to alleviate exploitation of wild salmon stocks, as capture fisheries landings remain little changed.

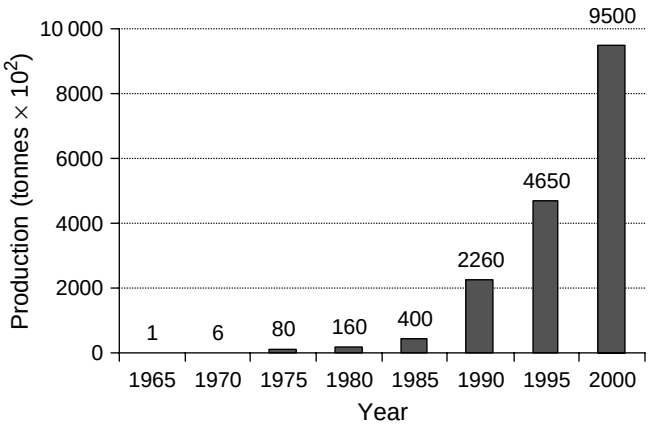

Figure 1 Farmed Atlantic salmon production, 1965–2000. FAO figures (FAO, 1999b) are used for the period 1985–1997; earlier data are from the literature

SALMON BIOLOGY AND FARMING METHODS

Although they begin life in streams and rivers, salmon are anadromous and migrate to the sea, where most of their growth occurs, after a variable period (months years) in freshwater. At the onset of sexual maturity, the fish migrate to their home rivers to spawn. The Pacific salmon die after

Table 1 Salmon and their distribution

Species	Common name	Distribution
Pacific salmon		
Oncorhynchus gorbuscha	Pink, humpy salmon	Rivers flowing into the rivers of the Pacific coast of the Northwest America and the Kamchatka peninsula, Russia
O. nerka	Sockeye	
O. kisutch	Coho, silver	
O. keta	Chum, dog	
O. tschawytscha	Spring, chinook, king	
O. masou	Masu, cherry salmon	Rivers of northern Hokkaido and the Manchuria peninsula
Atlantic salmon		
Salmo salar	Atlantic salmon	Rivers of countries bordering both sides of the northern Atlantic

spawning. Atlantic salmon, however, may return several times to breed. The farming cycle is species and location specific, but is described for Atlantic salmon. Captive, sexually mature broodstock are stripped of eggs and milt in late autumn, the gametes mixed and the fertilized eggs transferred to a hatchery. The eggs hatch in spring and, once the yolk sac has been absorbed, the fish are transferred to tanks and fed on artificial pelleted diets. By the autumn, some 6 months after hatching, a bimodal size distribution is apparent, the larger fish indicating their readiness to smolt and transfer to seawater the following spring. Thus, by the time they are 1 year old, and weighing 35 80 g, the majority of fish will be ready to be transferred to seawater cages or tanks.

More than 90% of farmed salmon production is derived from floating net cages anchored in sheltered inshore areas, such as the fjords of Norway and Chile, the sea lochs of Scotland and sheltered bays and loughs in Ireland. Growth in the sea is rapid. Fish are fed on a largely fishmeal and fish oil-based pelleted diet and can attain a weight of up to 2 kg after one sea winter. Disease and predators (birds, seals and sea lions) take their toll. The tremendous increases in production have led to increasingly saturated markets, driving down prices. Shrinking profit margins have led to wide-scale vertical integration of the industry (i.e., from hatcheries, through production, processing and marketing) and dominance by multinational companies. Production economics have led to year-round production of smolts through photoperiod manipulation, improved diets and feeding methods.

SALMON FARMING AND THE ENVIRONMENT

The relationship between aquaculture and the environment is described elsewhere (*see* Aquaculture and Environment: Global View from the Tropics to High Latitudes, Volume 3; Aquaculture in Asia, Volume 3). Critics point to salmon farming s reliance on industrial fisheries products for food, and the wastes (uneaten food, fecal and urinary products, chemotherapeutants, pathogens and feral (escaped) fish) that are released into the marine environment.

Salmon farming remains almost entirely reliant on fishmeal and fish oil-based diets. Approximately five tonnes of fish are required to make one tonne of fishmeal. Commercial diets are composed of approximately 45% fishmeal and 25% fish oil and as a result it takes something like 2.8 tonnes of fish to produce 1 tonne of salmon. Although salmon farming is a net consumer of fish (Naylor *et al.*, 1998), it may be argued that the fish reduced to fishmeal has little other commercial value than as a source of animal food. It is also a moot point whether farming of salmon may be more energy efficient than the exploitation of wild salmon stocks by fisheries. However, within the aquaculture sector, salmon farming is one of the more important consumers of fishmeal and fish oil, arguably adding to pressures on already fully and over-exploited wild fish stocks (see FAO, 1999a for review of capture fisheries stocks).

Salmon farming wastes are derived from uneaten food, the products of digestion (feces) and metabolic activity (urinary products), and the chemicals used in the treatment of disease and prevention of fouling on the cage nets. Cages rely on maximizing the free exchange of water with the external aquatic environment in order to maintain good water quality to sustain fish growth. However, as a result, the wastes discharged from the cages freely enter the environment.

Waste emissions may be estimated by two methods: direct measurement and mass balance modeling. The former is difficult and time consuming, requiring deployment of sediment traps and analysis of recovered material. Provided that the food conversion ratio (FRC) (amount of food fed/net production of fish) and nutrient content of food and fish flesh are known, nutrient wastes from salmon farms can be estimated by mass balance (Equation 1):

$$X = (\mathrm{FCR} \times \mathrm{A}) - B \quad (1)$$

where X is the nutrients lost to the environment (kg tonnes^{-1}), A is the nutrient content of fish food (kg tonnes^{-1}) and B is the nutrient content of fish flesh (kg tonnes^{-1}).

With improvements in diet formulation, feed technology and feeding methods, nutrient losses per unit production have declined over time. Today, something like 50 60 kg total-nitrogen and 7 9 kg total-phosphorus per tonne farmed salmon production are released into the environment by European salmon farms, less than one-third of the nutrient inputs associated with the industry 25 years ago (see Black, 1998, for review). Such calculations are limited in their usefulness as they give little information on the form of wastes or their bioavailability. However, by including information on uneaten food and by modeling growth and production over time, more detailed information on waste discharges can be derived.

Wastes are principally in one of two forms: particulate (uneaten food and feces) and dissolved (urinary products, leachates from feed and feces). The denser food particles tend to settle quickly and impact on the seabed close to the cages while the less dense feces settle farther from the cages (Chen *et al.*, 1999a, b). Impacts on the environment, especially the benthos, are readily discernible. Sediments under and immediately adjacent to salmon cages typically show signs of organic enrichment, with increased carbon and nitrogen levels (Black, 1998; Midlen and Redding, 1998). Considerable effort has been put into the development of models that can predict the fate of particulate wastes from salmon farms (Silvert, 1994), a pre-requisite to

the appropriate siting and sizing of cage farms. The effects of organic enrichment are to change benthic community composition and metabolism. Typically, macroinvertebrate abundance changes with degree of enrichment, abundance being generally highest at moderate levels of enrichment. There is a decrease in macroinvertebrate community diversity close to the cages and a gradual recovery to background levels as one moves away from the source of the pollution. Certain species, indicative of high levels of organic material, such as *Capitella capitata*, dominate community composition near the cages. Changes in benthic community diversity with distance from cages at a Scottish Atlantic salmon farm site are shown in Figure 2. The zone of impact is dependent upon size of farm, waste inputs, prevailing currents and depths, but typically extends for 25 120 m along the principal current axis (*see* **Aquaculture and Environment: Global View from the Tropics to High Latitudes**, Volume 3).

Copper-based antifoulants are still used on many salmon farms. Copper gradually leaches into the seawater environment and particles of copper-based paints can also be detected in sediments, although sediment concentrations remain low. Farmed salmon have proven susceptible to a range of bacterial diseases such as furunculosis and vibriosis. Gradually, however, reliance on antimicrobial compounds has been superseded by use of vaccines. These have seen quantities in Norway in 1999, for example, fall to 1% of their 1987 value, despite a 10-fold increase in salmon production over the intervening years (see Weston, 1996, for review of situation to 1993).

Some salmon-producing countries have serious problems associated with ectoparasitic copepod (*Caligus elongatus*, *Lepeophtheirus salmonis*) infections and are reliant on treatment with specially formulated pesticides. These

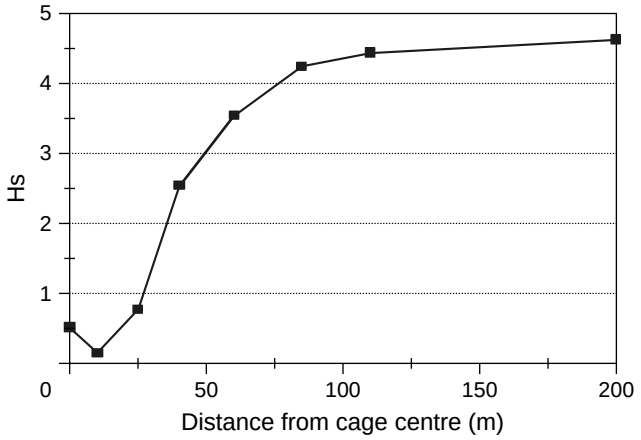

Figure 2 Diversity (Shannon–Weiner Index, Hs) for sediment macrofaunal communities versus distance at a salmon cage site, Scotland. The lower the diversity index value, the more dominated the community is by a few species

are used in two forms: bath and in-feed treatments. The bath treatment *dichlorvos*, for example, is introduced into an enclosed area through which the infected sh swim. Following treatment, the drug is released into the environment. Concerns about its environmental impacts (Lebris *et al.*, 1995; McHenery *et al.*, 1996) have led to the development of in-feed alternatives that are incorporated into the pelleted salmon diets. Release to the environment is from uneaten food or in fecal or excretory material and takes place over a longer time period. However, little is yet known about the ecotoxicology of these compounds. More environmentally benign alternatives, such as hydrogen peroxide and the use of the cleaner *wrasse*, have not proven suf ciently practicable to be widely adopted.

Fish escape from cages in small numbers as a result of day-to-day management of stock. Periodic mass releases, involving tens of thousands of salmon, can also happen as a result of storm damage or vandalism (Beveridge, 1996). In Chile, salmon are exotic and the fate and impact of feral farmed salmon on wild shes are unknown (Buschmann *et al.*, 1996). Atlantic salmon, were introduced to British Columbia for farming purposes in the late 1980s and it is now apparent that feral sh are appearing in sheries catches (McKinnell *et al.*, 1997) and are breeding in the rivers. Even within the home range of the Atlantic salmon, there are concerns about the impacts of feral farmed sh. In Norway, in 1997, more than 50% of Atlantic salmon recorded as caught by shermen were of farmed origin, while in the Faroe islands, as many as 60% of recorded salmon catches in recent years are of farmed origin (Hansen *et al.*, 1999). Genetically distinct, non-interbreeding populations of salmon occur in each river system. The fear is that feral farmed salmon will inter-breed with local populations, introducing genes that reduce the tness of individuals and putting the population at risk. A number of studies have shown escaped farmed salmon can cause long-term genetic changes in natural populations that affect both single-locus and highly heritable quantitative traits, such as growth and sea age of maturity (McGinnity *et al.*, 1997). However, while under some circumstances such changes may lead to reduced tness and productivity, declines in wild stocks are almost certainly due to a complex interaction of factors, including over- shing, habitat modi cation and climate change.

REGULATION OF THE INDUSTRY

Regulation of salmon farming varies from country to country. In Scotland, for example, regulation is governed by implementation of Directives from the European Commission in Brussels. This requires that an Environmental Impact Assessment is conducted by a competent body for each new salmon farm site >100 tonnes biomass or increase in size of an established farm. In addition, as ef uent from

salmon cages is considered an industrial discharge, it is modeled to estimate environmental impact and the impacts monitored by government regulators, such as the Scottish Environment Protection Agency, in the same way as effluents from other industries. Use of pesticides in salmon farming is carefully controlled in Scotland, with each farm site requiring a discharge consent for each chemical that it intends to use. Environmental regulation is usually enforced by granting a maximum production biomass of fish for each site, but may also take account of environmental management procedures, such as the introduction of a fallowing regime. This inevitably controls the amount of effluent entering the environment and allows site recovery between fish production cycles.

Careful site selection is an important part of the regulatory process, allowing new fish farms to be located in areas where environmental capacity will not be exceeded. Selection criteria include projected size of the fish farm (in terms of both production tonnage and area), water depth, water movement, other uses of the water body, proximity to other developments and whether the site is environmentally sensitive (in conservation areas or important wild salmon and trout streams).

Biomass Burning

Joel S Levine
NASA Langley Research Center, Hampton, VA, USA

In the preface to the book, One Earth, One Future: Our Changing Global Environment, *published by the National Academy of Sciences (1990), Dr Frank Press, the President of the Academy writes:*

> *Human activities are transforming the global environment, and these global changes have many faces: ozone depletion, tropical deforestation, acid deposition, and increased atmospheric concentrations of gases that trap heat and may warm the global climate.*

It is interesting to note that all four global change faces identi ed by Dr Press have one common thread - they are all caused by or related to biomass burning.

Biomass burning also includes vegetation burning is the burning of living and dead vegetation for land-clearing and land-use change, or natural, lightning-induced burning. The bulk of the world's biomass burning occurs in the tropics - in the tropical forests of South America and Southeast Asia and in the savannas of Africa and South America. However, a signi cant amount of biomass burning occurs in the boreal forests of Russia, Canada and Alaska. The majority of the biomass burning, primarily in the tropics (perhaps as much as 90%) is believed to be human-initiated, with natural res triggered by atmospheric lightning only accounting for on the order of about 10% of all res (Andreae, 1991). Biomass burning has been identi ed as a signi cant source of gases and particulates to the regional and global atmosphere.

Biomass burning is an important process of global change for several reasons, including:

1. *Biomass burning is a signi cant source of gases and particulates released to the atmosphere.*
2. *Carbon dioxide (CO_2) and methane (CH_4) produced by biomass burning are greenhouse gases (GHG) that trap heat and may warm the global climate.*
3. *Methyl bromide (CH_3Br) produced by biomass burning leads to the photochemical destruction of ozone in the stratosphere.*
4. *Nitric oxide (NO) produced by biomass burning leads to the photochemical production of nitric acid (HNO_3), the fastest growing component of acid precipitation.*
5. *Atmospheric aerosols or particulates produced by biomass burning absorb and scatter incoming solar radiation, and, hence, impact climate.*
6. *Biomass burning impacts the biogeochemical cycling of nitrogen (N) and carbon (C) compounds from the biosphere to the atmosphere.*
7. *Biomass burning impacts the hydrological cycle by perturbing precipitation run-off and evaporation.*
8. *Biomass burning alters the re ectivity and emissivity of the land cover and, hence, impacts the radiation budget of the land/atmosphere system.*
9. *Biomass burning destroys ecosystems, primarily in the tropics, and, hence, leads to loss of biodiversity and extinction of both ora and fauna.*

10. Particulates produced during biomass burning can lead to a signi cant decrease in atmospheric visibility.
11. Particulates produced during biomass burning and released into the atmosphere can result in signi cant respiratory health problems.

BIOMASS BURNING AS A SOURCE OF GASES AND PARTICULATES TO THE ATMOSPHERE

Biomass burning is a significant global source of gases and particulates to the atmosphere (Crutzen *et al.*, 1979, Seiler and Crutzen, 1980, Crutzen and Andreae, 1990, Levine *et al.*, 1995). Laboratory biomass burning experiments conducted by Lobert *et al.* (1991) have identi ed the various carbon (C) (Table 1) and nitrogen (N) (Table 2) compounds released to the atmosphere by burning. The exact nature and quantity of the gaseous and particulate emissions resulting from biomass burning depend on the particular ecosystem undergoing burning. Lobert *et al.* (1991) used biomass material from several different ecosystems in their laboratory experiments. To quantify the gaseous and particulate emissions from a particular ecosystem, eld measurements are required. Some of the eld experiments to quantify biomass burning in diverse ecosystems are outlined in the following section. The major gases produced during the biomass burning process include carbon dioxide (CO_2), carbon monoxide (CO), methane (CH_4), oxides of nitrogen (NO_x = nitric oxide (NO) + nitrogen dioxide, NO_2), and ammonia (NH_3). Carbon dioxide and methane are GHG, which trap Earth-emitted infra-red radiation and lead to global warming. Carbon monoxide, methane, and the oxides

of nitrogen lead to the photochemical production of ozone (O_3) in the troposphere. In the troposphere, ozone is an irritant and harmful pollutant, and in some cases, is toxic to living systems. Nitric oxide leads to the chemical production of nitric acid (HNO_3) in the troposphere. Nitric acid is the fastest growing component of acidic precipitation. Ammonia is the only basic gaseous species that neutralizes the acidic nature of the troposphere. Particulates, small (usually about 10 μm or smaller) solid particles, such as smoke or soot particles, are also produced during the burning process and released into the atmosphere. These solid particulates absorb and scatter incoming sunlight and hence impact the local, regional, and global climate. In addition, these particulates (specifically particulates 2.5 μm or smaller) can lead to various human respiratory and general health problems when inhaled. The gases and particulates produced during biomass burning lead to the formation of smog. The word smog was coined as a combination of smoke and fog and is now used to describe any smoky or hazy pollution in the atmosphere.

The study of biomass burning is truly a multidisciplined subject, which includes the following areas: fire ecology, fire measurements and modeling, fire combustion, remote sensing of fires, gaseous and particulate emissions from fires, the atmospheric transport of these emissions and the chemical and climatic impacts of these emissions. Over the last two decades, biomass burning has been the subject of many hundreds of papers in scientific journals and nine dedicated volumes (Goldammer, 1990; Levine, 1991; Crutzen and Goldammer, 1993; Goldammer and Furyaev, 1996; Levine, 1996a,b; van Wilgen *et al.*, 1997; Innes *et al.*, 2000; and Kasischke and Stocks, 2000).

BIOMASS BURNING FIELD EXPERIMENTS

Over the last decade, a series of biomass burning field experiments have been conducted to measure and quantify the gaseous and particulate emissions produced by biomass burning in diverse ecosystems. These field experiments also quantified biomass loading, before and after burning, the fire efficiency, the combustion efficiency, the fire temperature and energy released, the fire spread rate, the gaseous and particulate emissions produced during the fire and released to the atmosphere, and the impact of burning on the local ecosystem. These measurable parameters are all ecosystem-dependent. Biomass burning field experiments have been conducted in various ecosystems in Africa, South America, the Pacific Northwest US and Russia. Most of these experiments were planned and implemented under the auspices of the Biomass Burning Experiment (BIBEX), a research activity of the International Global Atmospheric Chemistry (IGAC) Project, part of the International Geosphere-Biosphere Program (IGBP). Some of these experiments are:

1. Africa: South African Fire-Atmosphere Research Initiative (SAFARI) 1992 and 2000, Transport and Atmospheric Chemistry near the Equator-Atlantic (TRACE-A), Experiment for Regional Sources and Sinks of Oxidants (EXPRESSO);
2. South America: Transport and Atmospheric Chemistry near the Equator-Atlantic (TRACE-A);
3. Pacific Northwest US: Smoke, Clouds, and Radiation-C (SCAR-C); and
4. The Bor Forest Island Experiment in Krasnoynarsk, Russia.

ENHANCED BIOGENIC SOIL EMISSIONS OF NITROGEN AND CARBON GASES: A POST-FIRE EFFECT

Measurements have shown that in addition to the instantaneous production of trace gases and particulates resulting from the combustion of biomass matter, burning also enhances the biogenic emissions of NO, nitrous oxide (N_2O) and CO from soil. It is believed that enhanced biogenic soil emissions of NO and N_2O are related to increased concentrations of ammonium (NH_4^+) found in soil following burning. Ammonium, a component of the burn ash is the substrate in nitrification, which is the microbial process believed responsible for the production of nitric and nitrous oxide. The post-fire enhanced biogenic soil emissions of NO and N_2O may be comparable to or even surpass the instantaneous production of these gases during biomass burning.

BIOMASS BURNING AND ATMOSPHERIC NITROGEN AND OXYGEN

Biomass burning is both an instantaneous source (the real time combustion of biomass) and a long-term source (enhanced biogenic soil emissions) of gases to the atmosphere. These gases impact both the chemistry of the troposphere and stratosphere and the biogeochemical cycling of nitrogen (N_2) and oxygen (O_2), the two major constituents of the atmosphere. Through the process of nitrogen fixation, molecular nitrogen is transported to the surface in the form of fixed nitrogen, i.e., ammonium (NH_4^+) and nitrate (NO_3^-). Nitrogen fixation results from both natural processes (biological fixation in root modules in certain agricultural crops and atmospheric lightning) and human processes (the production of nitrogen fertilizer and high temperature combustion). The world s use of industrially fixed nitrogen fertilizer has increased from about 3 teragrams (Tg) of N $year^{-1}$ in 1940 to about 75 Tg N $year^{-1}$ in 1990. The fixed nitrogen in the forms of NH_4^+ and NO_3^- is returned to the atmosphere mainly in the form of N_2, with smaller amounts of N_2O, and still smaller amounts of NO by denitrification and in the form of NO by nitrification.

Burning or pyro-denitrification may also be an important source of nitrogen, mostly in the form of N_2, from the biosphere to the atmosphere. The problem is that it is difficult to quantify the amount of N_2 released during burning (Lobert *et al.*, 1991), however, biomass burning or pyro-denitrification may prove to be an important process in the recycling of nitrogen compounds from the biosphere to the atmosphere.

Burning impacts the concentration of atmospheric oxygen in two ways. Carbon released during the burning of biomass combines with atmospheric oxygen to form CO_2. Hence, burning is a sink for atmospheric oxygen. In addition, biomass burning destroys the very source of atmospheric oxygen its production in the biosphere via the process of photosynthesis in the world s forests.

GEOGRAPHICAL DISTRIBUTION OF BIOMASS BURNING

Areas of biomass burning are varied and include tropical savannas, tropical, temperate and boreal forests and agricultural lands after the harvest. The burning of fuelwood for domestic use is another source of biomass burning. Much of our information on the geographical distribution of biomass burning is based on burning in the tropics, particularly South America, Africa and Southeast Asia. Considerably less information is known about biomass burning in the boreal forest.

BURNING IN THE WORLD'S BOREAL FORESTS

The world s boreal forests cover a little less than 17% of the Earth s land area, yet contain more than 30% of all the carbon present in the terrestrial biome. Although the combined tropical and temperate forests cover almost twice the land area as the boreal forest, the boreal forest contains 20% more carbon than the other two forests combined (Kasischke and Stocks, 2000). There are several important reasons that burning in the world s boreal forests is very important:

1. The world s boreal forests are very susceptible to global warming. Small changes in the surface temperature can significantly influence the ice/snow/albedo feedback. Thus, infrared absorption processes by fire-produced GHGs, as well as fire-induced changes in surface albedo and infrared emissivity are more environmentally significant than in the tropics.
2. In the world s boreal forests, global warming may result in warmer and drier conditions. This in turn may result in enhanced frequency of fire and the accompanying enhanced production of GHGs that will amplify the greenhouse effect.
3. Fires in the boreal forests are perhaps the most energetic in nature. The average fuel consumption per unit area in the boreal forest is on the order of 25 000 kg hectare^{-1} (1 ha = 2.47 acres), which is about an order of magnitude greater than in the tropics. Large boreal forest fires typically spread very quickly, most often as crown fires. Large boreal forest fires release enough energy to generate convective smoke columns that routinely reach well into the troposphere, and on occasion may directly penetrate across the tropopause. The tropopause is at a minimum height over the world s boreal forests. As an example, a 1986 forest fire in Northwestern Ontario (Red Lake) at times generated a convective smoke column 12 13 km, penetrating the tropopause.
4. The cold temperature of the troposphere over the world s boreal forests results in very low levels of tropospheric water vapor. The deficiency of tropospheric water vapor and the scarcity of incoming solar radiation over most of the year results in very low photochemical production of the hydroxyl radical (OH) over the boreal forests. The OH radical is the overwhelming chemical scavenger in the troposphere and controls the atmospheric lifetime of most tropospheric gases. The very low concentrations of the OH radical over the boreal forests will result in enhanced atmospheric lifetimes for most tropospheric gases, including the gases produced by fire combustion. Hence, gases produced by burning, such as CO, CH_4, and the oxides of nitrogen will have enhanced lifetimes over the boreal forest (*see* OH–Radical: is the Cleansing Capacity of the Atmosphere Changing?, Volume 2).

It has generally been believed that biomass burning is primarily a tropical phenomenon. This is because most of the information that we have on the geographical and temporal distribution of biomass burning is largely based on tropical burning. Due to poor satellite coverage, among other things, there is very little information available on the geographical and temporal distribution on biomass burning in the boreal forests, which cover about 25% of the world s forests. To illustrate how our knowledge of the geographical extent of burning in the world s boreal forests has increased in recent years, consider the following: Early estimates based on surface fire records and statistics suggested that as much as 1.5 million ha of boreal forests burn annually (Seiler and Crutzen, 1980). One of the largest fires ever measured occurred in the boreal forests of the Heilongjiang Province of Northeastern China in May 1987. In less than four weeks, more than 1.3 million ha of boreal forest were burned (Cahoon *et al.*, 1994). At the same time, extensive fire activity occurred across the border in Russia, particularly in the area east of Lake Baikal between the Amur and Lena rivers. Estimates based on imagery from the National Oceanic and Atmospheric Administration/Advanced Very

High Resolution Radiometer (NOAA/AVHRR) indicate that 14.446 million ha (35.697 million acres) in China and Siberia were burned in 1987 (Cahoon *et al.*, 1994).

While 1987 was an extreme fire year in Eastern Asia, the sparse database may suggest a trend. Is burning in the boreal forests increasing with time, or are satellite measurements providing more accurate data? Satellite measurements are certainly providing a more accurate assessment of the extent and frequency of burning in the world s boreal forests. However, it is important to point out that if global warming becomes a reality, predicted warmer and drier conditions in the world s boreal forests will result in more frequent and larger fires, and increased burning may have an amplifying effect on global warming!

A recent study (Kasischke *et al.*, 1999) has provided new information of burning in the world s boreal forests:

1. Fires in the boreal forest covering at least 100 000 ha are not uncommon.
2. In the boreal forests of North America, most fires (>90%) are crown fires. The remainder are surface fires. Crown fires consume much more fuel (30 40 tons of biomass material per ha burned) than surface fires (8 12 tons of biomass material per ha burned).
3. The fire record for North America over the past three decades clearly shows the episodic nature of fire in the boreal forests. Large fire years occur during extended periods of drought, which allow naturally ignited fires (i.e., lightning ignited fires) to burn large areas. Since 1970, the area burned during six episodic fire years in the North American boreal forest was 6.2 million ha year^{-1}, while 1.5 million ha year^{-1} burned in the remaining years. There is evidence that a similarly episodic pattern of fire may also exist in the Russian boreal forest.
4. The fire data in the North American boreal forest show a significant increase in the annual area burned over the past three decades, with an average 1.5 million ha year^{-1} burning during the 1970s and 3.2 million ha year^{-1} burning during the 1990s. This increase in burning corresponds to rises of 1.0 1.6 °C over the same period. The projected 2 4 °C increase in temperature due to projected increases in GHGs should result in high levels of fire activity throughout the world s boreal forests in the future.
5. During typical years in the boreal forests, the amounts of biomass consumed during fire ranges between 10 and 20 tons ha^{-1}. During the drought years with episodic fires, the amounts of biomass consumed during biomass burning may be as high as 50 60 tons ha^{-1}. Assuming that biomass is about 50% carbon by mass, such amounts would release 450 600 Tg C globally. These amounts are considerably higher than the often-quoted value for total carbon released by biomass burning in the world s boreal and temperate forests of 130 Tg C globally (Andreae, 1991, see Table 3).

ESTIMATES OF GLOBAL BURNING AND GLOBAL GASEOUS AND PARTICULATE EMISSIONS

Global estimates of the annual amounts of biomass burning from these sources are estimated in Table 3 (Andreae, 1991). Biomass matter is about 45% by weight composed of carbon. Table 3 also gives estimates of the carbon released (Tg C year^{-1}) by the burning of this biomass. Combining estimates of the total amount of biomass matter burned per year (Table 3) with measurements of the gaseous and particulate emissions from biomass burning (Tables 1 and 2) permits estimates of the global production and release into the atmosphere of gases and particulates from burning. Estimates of the global contribution of biomass burning are summarized in Table 4 (Andreae, 1991). The data in Tables 3 and 4 clearly indicate that biomass burning is a truly global process of major importance in the global budgets of atmospheric gases and particulates.

A CASE STUDY: THE CALCULATION OF GASEOUS AND PARTICULATE EMISSIONS FROM THE FOREST AND PEAT FIRES IN KALIMANTAN AND SUMATRA, INDONESIA, IN 1997

The years 1997 1998 saw a series of extensive and widespread El-Nino-related fires in Southeast Asia, South America, Africa, Mexico, Russia, and Florida. The fires in Southeast Asia were particularly extensive and widespread. Throughout Southeast Asia, including Indonesia, the major cause of forest fires is controlled burning for land clearing and land-use change activities. This burning has been an

annual practice for over 100 years. Over the last 15 years, burning for land clearing has increased, as large rubber and oil palm plantations use burning as a fast and inexpensive method of large-scale land clearing. However, forest fires in Indonesia are unique in that they often ignite fires in the underlying peat or coal layers. About 50%, or approximately 269 730 km^2 of Kalimantan and about 35%, or 183 435 km^2 of Sumatra, are underlain with peat and coal. Significant, but smaller deposits of peat and coal are also found on many of the other Indonesian islands, including Java, Southern Sulawesi, Madura and Irian Jaya.

During the last 15 years of burning in Indonesia, it became apparent that large-scale regional episodes of smoke, locally known as haze, were produced. Fires for land clearing produced regional haze conditions in 1982, 1991, and 1994. In 1997, the El Nino/Southern Oscillation once again brought severe drought conditions to Southeast Asia and contributed to uncontrolled fires which produced severe regional haze and air pollution conditions. The 1997 1998 forest and peat/coal fires in Indonesia were described as one of the most broad-ranging environmental disasters of the century.

Some of the consequences of the fires in Indonesia fires included: (1) more than 200 million people exposed to high levels of air pollution and particulates produced during the fires; (2) more than 20 million smoke-related health problems; (3) fire-related damage in excess of $4 billion; (4) the crash of a commercial airliner (Garuda Airlines Airbus 300-B4 on September 26th 1997) in Sumatra due to very poor visibility on landing with 234 passengers killed; (5) the collision of two ships at sea due to poor visibility in the Strait of Malacca, off the coast of Malaysia, on September 27th, 1997 with 29 crew members killed.

International concern about the environmental and health impacts of these fires resulted in a series of United Nations (UN) workshops and reports, including: The World Meteorological Organization (WMO) Workshop on Regional Transboundary Smoke and Haze in Southeast Asia, Singapore, June 2nd 5th, 1998 (Carmichael, 1999), The World Health Organization (WHO) Health Guidelines for Forest Fires Episodic Events, Lima, Peru, October 6th 9th, 1998, (Schwela *et al.*, 1999) and the United Nations Environmental Programme (UNEP) Report on Wildland Fires and the Environment: A Global Synthesis (Levine, 1999).

Calculation of Gaseous and Particulate Emissions from Vegetation and Peat Fires

To assess both the environmental and health impacts of these fires, the gaseous and particulate emissions produced during the fire and released into the atmosphere must be modeled. The calculation of gaseous and particulate emissions from biomass burning or vegetation fires can be

calculated using a form of an expression from Seiler and Crutzen (1980) for each burning ecosystem/terrain type i (where i is the rain forests, dry forests, plantations, chaparral, grasslands, agricultural lands, wetlands, peatlands, etc.):

$$M_i = A_i \times B_i \times E_i \quad (1)$$

where M_i is the total mass of biomass or vegetation consumed by burning (tons) in ecosystem i, A_i is the area burned in ecosystem i (km^2), B_i is the above ground biomass loading in ecosystem i (tons km^{-2}), and E_i is the burning ef ciency of vegetation in ecosystem i (dimensionless). For each ecosystem i, the total mass of carbon $(M(C))_i$ released to the atmosphere during burning is related to M_i by the following expression:

$$M(C)_i = C \times M_i \text{ (tons of carbon)} \quad (2)$$

C is the mass percentage of carbon in the biomass. For most vegetation, $C = 0.45$ (Andreae, 1991). The mass of CO_2 ($M(CO_2)_i$) released during the re is related to $M(C)_i$ by the following expression:

$$M(CO_2)_i = CE_i \times M(C)_i \quad (3)$$

The combustion ef ciency (CE_i) is the fraction of carbon emitted as CO_2 relative to the total carbon compounds released during the re in ecosystem i. For most vegetation res, $CE = 0.90$ (Andreae, 1991).

Once the mass of CO_2 produced by burning is known, the mass of any other species, j, in ecosystem i, X_{ij} ($M(X_{ij})$), produced by burning and released to the atmosphere can be calculated with knowledge of the CO_2-normalized *species emission ratio* ($ER(X_{ij})$). The emission ratio is the ratio of the production of species X_{ij} to the production of CO_2 in the re in ecosystem i. The mass of species, X_{ij} is related to the mass of CO_2 by the following expression:

$$M(X_{ij}) = ER(X_{ij}) \times M(CO_2)_i \text{ (tons of element } X_i) \quad (4)$$

where $X_j = CO$, CH_4, non-methane hydrocarbons, NO_x, NH_3, etc. Typical values for emission ratios for vegetation and peat res are given in Table 5.

An alternate approach involves the use of the *species emission factor* ($EF(X_{ij})$), instead of the species emission ratio ($ER(X_{ij})$). The emission factor gives the mass of gas or particulate produced per mass of biomass consumed by burning in units of g kg^{-1}. To calculate the total particulate matter (TPM) released from vegetation res, we use the following expression:

$$TPM = M \times P \text{ (tons of carbon)} \quad (5)$$

where P is the conversion of biomass matter to particulate matter during burning. For the burning of most vegetation, $P = 20$ tons of TPM $kton^{-1}$ of biomass consumed by re.

Table 5 Some typical emission ratios for tropical forest fires and peat fires

Species	Tropical forest fires (%)	Peat fires (%)
CO_2	90.00	77.05
CO	8.5	18.15
CH_4	0.32	1.04
NO_x	0.21	0.46
NH_3	0.09	1.28
O_3	0.48	1.04
TPM[a]	20 tons tons $kton^{-1}$	35 tons $kton^{-1}$

[a] TPM, TPM emission ratios are in units of tons $kton^{-1}$ (tons of TPM/kiloton of biomass or peat material consumed by fire).

Total Area Burned and Biomass Consumed

Perhaps the major uncertainties in the calculation of gaseous and particulate emissions resulting from res involve poor or incomplete information about four re parameters: (1) the area burned (A); (2) the ecosystem or terrain that burned, i.e., forests, grasslands, agricultural lands, peat lands, etc.; (3) the biomass loading (B), i.e., the amount of biomass per unit area of the ecosystem prior to burning; and (4) the re ef ciency (C), i.e., the amount of biomass in the burned ecosystem that was actually consumed by burning. The area burned can be determined through the use of satellite measurements. Some operational satellite systems to estimate area burned, as well as monitor active res, are listed in Table 6.

Liew *et al.* (1998) analyzed 766 SPOT (Système Pour l Observation de la Terre) quicklook images with almost complete coverage of Kalimantan and Sumatra from August December, 1997. Liew *et al.* (1998) estimated the burned area in Kalimantan to be 30 600 km^2 and the burned area in Sumatra to be 15 000 km^2, for a total burned area of 45 600 km^2. For the calculations illustrated in this article, we have used the Liew *et al.* (1998) estimate for total burned area in Kalimantan and Sumatra of 45 600 km^2 (This is greater than the total area of Denmark or Switzerland). The estimate of Liew *et al.* (1998) represents only a lower limit estimate of the area burned in Southeast Asia in 1997, since the SPOT data only covered Kalimantan and Sumatra and did not include res on the other Indonesian islands of Irian Jaya, Sulawesi, Java, Sumbawa, Komodo, Flores, Sumba, Timor, and Wetar or the res in the neighboring countries of Malaysia and Brunei.

What is the nature of the ecosystem/terrain that burned in Kalimantan and Sumatra? In October 1997, NOAA satellite monitoring produced the following distribution of re hot spots in Indonesia (UNDAC, 1998): agricultural and plantation areas: 45.95%; bush and peat soil areas: 24.27%; productive forests: 15.49%; timber estate areas: 8.51%; protected areas: 4.58%; and transmigration sites: 1.20% (the three forest/timber areas add up to a total of 28.58% of the area burned). While the distribution of re hot spots is not

Table 6 Some current operational satellite fire monitoring systems

1. NOAA/AVHRR Global 1 km imaging systems. Monitors active fires and burned area
2. DMSP (Defense Meteorological Satellite Program)/OLS (Operational Linescan System): Global night-time low light sensor. Monitors active fires
3. GOES (Geostationary Operational Environmental Satellite) Imager: Continental high temporal frequency, coarse spatial resolution geostationary imaging. Monitors active fires and smoke
4. ERS (European Remote Sensing Satellite)/ATSR (Along-Track Scanning Radiometer) (European Space Agency): Global 1 km imaging. Monitors active fires and burned areas
5. ERS/JERS (Japanese Earth Resources Satellite) SAR (Synthetic Aperture Radar) (European Space Agency/NASDA (National Space Development Agency of Japan): Global microwave high-resolution system. Monitors burned area
6. LANDSAT (Land Satellite) TM (Thematic Mapper)/MSS (Multispectral Scanner System): Local, high spatial frequency, low temporal frequency. Monitors burned area
7. SPOT (Système Pour l'Observation de la Terre) CNES (Centre National d'Etudes Spatiales): Local, high-spatial frequency, low-temporal frequency. Monitors burned area.
8. Terra Satellite (EOS-AM1)/Moderate Resolution Imaging Spectrometer (MODIS): Launched December 1999: Measures active fires and burned areas

an actual index for area burned, the NOAA satellite-derived hot spot distribution is quite similar to the ecosystem/terrain distribution of burned area deduced by Liew *et al.* (1998) based on SPOT images of the actual burned areas: agricultural and plantation areas: 50%; forests: 30%; and peat swamp forests: 20%. Since the estimates of burned ecosystem/terrain of Liew *et al.* (1998) are based on actual SPOT images of the burned area, their estimates were adopted in our calculations.

What is the biomass loading for the three terrain classifications identified by Liew *et al.* (1998)? Values for biomass loading or fuel load for various tropical ecosystems are summarized in Table 7. The biomass loading for tropical forests in Southeast Asia ranges from 5000 55 000 tons km^{-2}, with a mean value of 23 000 tons km^{-2}. However, in our calculations we have used a value of 10 000 tons km^{-2} to be conservative. The biomass loading for agricultural and plantation areas (mainly rubber trees and oil palms) of 5000 tons km^{-2} is also a conservative value (Liew *et al.*, 1998). A biomass loading value of 97 500 tons km^{-2} for the dry peat deposits 1.5 m thick was used (Supardi *et al.*, 1993). The combustion efficiency for forests is estimated at 0.20 and for peat is estimated at 0.50 (Levine and Cofer, 2000). Based on the discussions presented in this section, the values for burned area, biomass loading, and combustion efficiency, used in the calculations are summarized in Table 8.

Table 7 Biomass load range and burning efficiency in tropical ecosystems (Scholes *et al.*, 1996 and Supardi *et al.*, 1993)

Vegetation type	Biomass load range (tons km^{-2})	Burning efficiency
Peat	97 500	0.50
Tropical rainforests	5000–55 000	0.20
Evergreen forests	5000–10 000	0.30
Plantations	500–10 000	0.40
Dry forests	3000–7000	0.40
Fynbos	2000–4500	0.50
Wetlands	340–1000	0.70
Fertile grasslands	150–550	0.96
Forest/savanna mosaic	150–500	0.45
Infertile savannas	150–500	0.95
Fertile savannas	150–500	0.95
Infertile grasslands	150–350	0.96
Shrublands	50–200	0.95

Table 8 Parameters used in calculations of emissions from Southeast Asia fires[a]

1. Total area burned in Kalimantan and Sumatra, Indonesia in 1997: 45 600 km^2
2. Distribution of burned areas, biomass loading and combustion efficiency

A. Agricultural and plantation areas – 50%, 5000 tons km^{-2}, 0.20
B. Forests and bushes – 30%, 10 000 tons km^{-2}, 0.20
C. Peat swamp forests – 20%, 97 500 tons km^{-2}, 0.50

Results of Calculations: Gaseous and Particulate Emissions

The calculated gaseous and particulate emissions are summarized in Table 9. For each of the seven species listed, the emissions due to agricultural/plantation burning (A), forest burning (F), and peat burning (P) are given. The total (T) of all three components (A + F + P) is also given. The best estimates of total emissions are: CO_2: 191.485 million metric tons of C (Mt C); CO: 32.794 Mt C; CH_4: 1.845 Mt C; NO_x: 0.971 Mt N; NH_3: 2.585 Mt N; O_3: 7.100 Mt O_3; and TPM: 16.568 Mt C.

Scholes *et al.* (1996) calculated the biomass consumed by burning in 11 different ecosystems in another tropical ecosystem, southern Africa. Scholes *et al.* (1996) performed a detailed statistical analysis of the errors associated with the calculated values of biomass consumed by fire using a statistical procedure which assumes that all error terms (e) are independent. In the error analysis of Scholes *et al.* (1996), the total error (e_{total}), which corresponds to

Table 9 Gaseous and particulate emissions from the fires in Kalimantan and Sumatra in 1997 (for total burned area = 45 600 km^2) (Levine, 1999)[a]

	Agricultural/plantation fire emissions	Forest fire emissions	Peat fire emissions	Total fire emissions
CO_2	9.234 (4.617–13.851)	11.080 (5.54–16.62)	171.170 (85.585–256.755)	191.485 (95.742–287.226)
CO	0.785 (0.392–1.177)	0.942 (0.471–1.413)	31.067 (15.533–46.600)	32.794 (16.397–49.191)
CH_4	0.030 (0.015–0.045)	0.035 (0.017–0.052)	1.780 (0.89–2.67)	1.845 (0.922–2.767)
NO_x	0.023 (0.011–0.034)	0.027 (0.013–0.040)	0.921 (0.460–1.381)	0.971 (0.485–1.456)
NH_3	0.010 (0.005–0.015)	0.012 (0.006–0.018)	2.563 (1.281–3.844)	2.585 (1.292–3.877)
O_3	0.177 (0.088–0.265)	0.213 (0.106–0.319)	6.710 (3.35–10.06)	7.100 (3.55–10.65)
TPM	0.460 (0.23–0.69)	0.547 (0.273–0.820)	15.561 (7.780–23.341)	16.568 (8.284–24.852)

[a] Units of emissions: Mt of C for CO_2, CO, and CH_4; Mt of N for NO_x and NH_3; Mt of O_3 for O_3; Mt C of particulates; 1 Mt = 10^{12} g = 1 Teragram, Tg.

the 3-sigma (99%) confidence level, is estimated using the following expression:

$$e_{\text{total}} = (e^2_{\text{burned area}} + e^2_{\text{fuel load}} + e^2_{\text{combustion completeness}})^{1/2} \quad (6)$$

Scholes *et al.* (1996) assumed the following uncertainties for each calculation parameter: $e_{\text{burned area}} = 30\%$, $e_{\text{fuel load}} = 30\%$ and $e_{\text{combustion completeness}} = 25\%$. In the error analysis of the calculations presented in this article, the error associated with uncertainties in the emission ratio ($e_{\text{emission ratio}}$) (30%) has also been included. The uncertainties in the calculation parameters in the detailed error of analysis of Scholes *et al.* (1996) were adopted in this study, with the exception of the uncertainty in the burned area of 30%. The burned area determination used in Scholes *et al.* (1996) was based on satellite measurements of active fires that were converted to burned area, which is not a simple one-to-one transformation and introduces errors. The burned area determination used in this article was more straightforward since it was based on direct satellite photography of burned areas using SPOT images (Liew *et al.*, 1998). Hence, there is less uncertainty in this burned area determination and an uncertainty of 10% was assumed. (Liew *et al.* (1998) did not give a burned area uncertainty in their paper.) The calculated uncertainty in the emission calculations is 50.2%. The uncertainty range for each species emission is shown in parentheses under the best estimate value in Table 9.

However, it is important to re-emphasize that these emission calculations represent lower limit values since the calculations are only based on burning in Kalimantan and Sumatra in 1997. The calculations do not include burning in Java, Sulawesi, Irian Jaya, Sumbawa, Komodo, Flores, Sumba, Timor, and Wetar in Indonesia or in neighboring Malaysia and Brunei.

It is interesting to compare the gaseous and particulate emissions from the 1997 Kalimantan and Sumatra fires with those from the Kuwait oil fires of 1991, described as a major environmental catastrophe. Laursen *et al.* (1992) calculated the emissions of CO_2, CO, CH_4, NO_x, and particulates from the Kuwait oil fires in units of metric tons per day. The Laursen *et al.* (1992) calculations are summarized in Table 10. To compare these calculations with the calculations presented in this article for Kalimantan and Sumatra (Table 9), we have normalized our calculations by the total number of days of burning. The SPOT images (Liew *et al.*, 1998) covered a period of five months (August December, 1997) or about 150 days. For comparison with the Kuwait fire emissions, we divided our calculated emissions by 150 days. These values are summarized in Table 10. The gaseous and particulate emissions from the fires in Kalimantan and Sumatra significantly exceeded the emissions from the Kuwait oil fires. The 1997 fires in Kalimantan and Sumatra were a significant source of gaseous and particulate emissions to the local, regional, and global atmosphere.

Table 10 Comparison of gaseous and particulate emissions: the Indonesian fires (Levine, 1999) and the Kuwait oil fires (Laursen *et al.*, 1992)[a]

Species	Indonesian fires	Kuwait oil fires
CO_2	1.28×10^6	5.0×10^5
CO	2.19×10^5	4.4×10^3
CH_4	1.23×10^4	1.5×10^3
NO_x	6.19×10^3	2.0×10^2
Particulates	1.08×10^5	1.2×10^4

[a] Units of emissions: metric tons per day of carbon for CO_2, CO, and CH_4; metric tons per day of nitrogen for NO_x; metric tons per day for particulates; one million metric tons = 10^{12} (g = 1 Teragram, Tg).

Biomass Burning in Rural Homes in Tropical Areas

Phil O'Keefe

University of Northumbria at Newcastle, Newcastle, UK

Countries with low income, countries with unequal income distributions and countries with low levels of urbanization rely on signi cantly different energy carriers than richer countries. For the cooking, water heating and space

heating needs of some two billion people worldwide the dominant household energy consumption activities wood, crop residues and dung, collectively called biomass, are the dominant fuels. Per capita energy use is approximately one cubic meter per person per year.

Biomass accounts for about 80% of all household energy consumption in developing countries although consumption in urban areas is lower. Women and children are the primary collectors of fuelwood and other biomass energy sources. Air pollution indoors is a major by-product of the traditional use of biomass, which diminishes the quality of life, especially for women and young children.

Despite attempts to directly link biomass eld use with deforestation, the relationship is weak. The primary cause for deforestation is land clearance for agricultural purposes rather than cutting forests for biomass fuels. There is evidence of the negative impact of energy use on wood resources around cities.

The production, transport and distribution of biomass is generally a private sector business. The structure varies from country to country but it is mostly an informal sector activity. As investment needs have been small, biomass investment has been neglected by governments and international nancial institutions. Production costs of traditional fuels have been low because the opportunity cost of labor spent on collection is low and the full cost of reproducing biomass is not included in the price. This is not a small matter because biomass commerce in some cities exceeds electricity sales. Yet because it is a common property resource, there are some exaggerated fears that biomass could disappear, another example of The Tragedy of the Commons.

Directly addressing the biomass problem is dif cult. Fuelwood, usually gathered as a common property resource, is essentially rubbish. Wood needs to be cleared if agriculture is to take place. Dead wood also occurs naturally. Rarely do people cut whole trees, preferring to lop branches not least because they only have hand tools for felling. Rarely do they directly plant trees primarily for rewood. This suggests that, despite the increasing time required to gather biomass, people still consider biomass a cheap fuel that is readily available. It suggests, too, that people view trees as multipurpose, e.g., providing fruit, fodder, thatch and shade; trees only become fuel at the end of useful life, after serving these multipurpose ends.

The broad strategy to address the rural energy problem is to create an energy transition by moving people up the energy ladder (*see* **Biomass Use for Urban Fuels in Developing Countries**, Volume 3). Most conventional fuels, notably electricity and gas, are more expensive than biomass. As a consequence, the energy transition is slow and restricted to high value low intensity enduses such as domestic lighting. The transition will require the eradication of rural poverty.

In the biomass sector itself, there are two strategies available to address energy problems, supply enhancement and increased ef ciency of use. Supply enhancement has focused on four interventions, namely:

1. increased off-take from national parks rather than encouraging vegetation climax as a management goal;
2. plantations;
3. woodlots;
4. *agroforestry*, sometimes called *social forestry*.

The rst three interventions have been largely unsuccessful, not least because wood production is far from point of consumption. With plantations and woodlots, as well, the emphasis on the single exotic species does not t well to local consumption patterns of multipurpose trees. Agroforestry seems to hold the key, locating production in and around family farms. This, however, requires re-educating foresters and agricultural extensionists that trees enhance local livelihood systems.

The second strategy, ef ciency, has focused mainly on improved cooking stoves. These stoves, for which there are many competing designs, replace the traditional open hearths. Most designs have one thing in common an enclosed combustion chamber. That enclosure creates its own problems because, since most cooking is done in the late evening, the light from the open re is lost. Light is a major simultaneous enduse of open res, which is lost by enclosing combustion chambers. Traditional open res have other simultaneous enduses, such as boiling, cooking and space heating, that require designers to consider social, as well as physical, ef ciency. The most successful design has occurred in Africa, where a semi-enclosed stove, modeled on Asian stoves, sells well at urban bus depots for transfer to rural markets.

Developing an energy policy can start from its many practical and strategic advantages of biomass. Firstly, biomass is local and ts local livelihood systems. Secondly, unlike other hydrocarbon fuels, it is carbon (C) neutral and does not contribute to greenhouse gases. Most importantly, for developing countries, it is a saving on foreign exchange.

Biomass should be managed sustainably rather than being mined. The sustainability of the biomass resource can be enforced by:

- pricing biomass at its full reproduction cost rather than its short run exploitation costs;
- devolving management, and political control, to local communities;
- establishing legal instruments for controlled cutting.

Increased prices for biomass fuels will encourage the development and acceptance of more ef cient and less polluting combustion technologies. *See* **Agroforestry**, Volume 3.

Biomass Fuel Power Development

Rik Leemans

National Institute of Public Health and the Environment, Bilthoven, The Netherlands

Plants capture sunlight and use its energy to transform carbon dioxide (CO_2) and water (H_2O) into organic matter. The resulting biomass is the basis of all life on Earth. Traditionally, humans have strongly relied on biomass as a source for food, fuels, building materials and many other uses. During recent centuries, however, the role of biomass as the primary energy source has declined in favor of the more effective and seemingly unlimited fossil fuels.

Since the oil crisis in the 1970s, many countries have tried to develop an independent energy source. Consequently, the use of biomass as an energy carrier has emerged again. For example, Brazil set up an advanced program to produce ethanol from sugarcane, which is used as transportation fuel. The cane residues provide the energy needed to drive the production process. Other biomass programs have been developed in several countries but these have been less commercially viable (Johansson et al., *1993). Liquid fuels from cornstarch and rapeseed in temperate zones have been produced but this has not been very ef cient.*

Many different plant species act as biomass crops. The actual selection is dependent on environmental factors and the energy conversion technology. Traditionally, wood chips, manure and crop residues and other waste materials were used. Nowadays, dedicated energy crops consist of fast growing species, optimized to be cultivated under local conditions. These crops include short-rotation woody shrubs and trees, herbaceous plants, halophytes (in severe environments) and some annual crops, such as oilseeds. The woody and herbaceous biomass is generally transformed into heat or electricity in local plants. The ash is returned to the plantations as fertilizer. Sweden, for example, has developed an extensive system for city heating based on short-rotation willow plantations. Currently, the efficiency of converting biomass into energy is relatively low but this could increase by improved technologies, such as combined heat and electricity generation. A promising technology is to convert biomass into syngas (a mixture of carbon monoxide (CO) and hydrogen (H)) and subsequently use this to generate electricity in a fuel cell.

The increase in atmospheric carbon dioxide (CO_2) concentrations, due to the burning of fossil fuels and deforestation, has generated additional opportunities for modern biomass. The production of biomass withdraws CO_2 from the atmosphere, while its use releases this again. As such, biomass is carbon (C) neutral and contributes to reducing CO_2 emissions or stabilizing CO_2 concentrations. Many assessments of the future energy-carrier mix depict a larger share of modern biomass. The Intergovernmental Panel on Climate Change (IPCC), for example, has already projected a large increase in modern-biomass use in its 1992 scenarios (Pepper *et al.*, 1992). IPCC has further concluded (Watson *et al.*, 1996) that large-scale use of modern biomass and other renewables in combination with a doubled energy efficiency could cut CO_2 emissions by almost 90%. This conclusion was based on the application of known technologies. One of the underlying assumptions, however, is that the conversion of biomass in fuel cells will soon become possible. This means a rapid maturation and implementation of this new technology, which is unlikely.

The use of biomass has more advantages than only reduced CO_2 emissions (Hall and House, 1995). First, the sulfur (S) content of biomass is relatively low, so that burning provides low air-pollution levels, especially when this is done in controlled and efficient furnaces. Second, biomass can be cultivated in many different climates and on different soil and terrain types. The selection of biomass crops can be optimized for local production systems. Third, modern biomass cultivation can contribute to restoring degraded lands. Fourth, biomass crops can diversify farm systems, which result in more robust economic entities. Especially in developing countries, the cultivation of biomass could assist in generating additional income for local farmers. In the industrialized world, biomass could well become a major crop on agricultural land that is taken out of production. Modern biomass crops can easily be produced at small and intermediate scales. Fifth, modern biomass

crops could fulfill additional functions, such as erosion protection, shading, shelterbelts, windbreaks and providing natural habitats for biodiversity. Finally, large-scale use of modern biomass decreases the dependence of imported fossil fuels.

Despite the obvious advantages, disadvantages of modern biomass crops should not be neglected. First, biomass crops are bulky and their transportation requires energy, which reduces the overall energy efficiency. Modern biomass is therefore only transported over short distances and is most suitable for local applications. Modern biomass is thus not as versatile as fossil fuels. The likely future efficient conversion to gas or electricity reduces this disadvantage but requires large investments in research and developing the appropriate infrastructure, such as an electricity grid. Second, the large-scale cultivation of modern biomass requires land. In many regions land availability is a lesser issue because of current overproduction in the agricultural sector. Leftover land could well be used for modern biomass plantations. In developing regions, however, with an increasing demand for food due to larger populations and changing consumption patterns, land could become limited (*see* Biomass Burning in Rural Homes in Tropical Areas, Volume 3). Biomass plantations could well compete with food crops and/or pastures. The competitive abilities are strongly dependent on market prices of biomass and food and many other local environmental and cultural conditions. Competition for land has rarely been comprehensively assessed in studies on the feasibility of biomass crops. Finally, biomass crops generally require longer rotation times. This makes them more prone for disturbances, such as pest and fires. But proper management can probably overcome this.

To increase the share of modern biomass in the mix of energy carriers, research should focus on improving the conversion efficiency of modern biomass for producing heat, electricity, and liquid fuels. Additionally, growing modern biomass crops on a very large scale has consequences for competition with other land uses and possibly impacts on land degradation, deforestation and biodiversity. These impacts, unfortunately, are not very well studied. Overall, one should conclude that modern biomass could become a valuable and environmentally friendly energy carrier, which is truly renewable and can easily be adapted to local and regional conditions and circumstances. Most signs indicate an increased market share of modern biomass in many regions.

Biomass Use for Urban Fuels in Developing Countries

Phil O'Keefe
University of Northumbria, Newcastle, UK

Most of the world's urban population is in developing countries. Even Africa, largely unurbanized, has a larger urban population, some 250 million people, than that of North America. Over 600 million urban dwellers live in life threatening *or* health threatening *circumstances because of overcrowded housing, dangerous land sites and a lack of basic services. Energy is one such service. In developing countries, urban energy problems are dominated by the household and transport sectors.*

*In the household sector, the single largest enduse of energy is cooking. Biomass resources (*see ***Biomass Fuel Power Development****, Volume 3) predominate, principally charcoal and wood. Charcoal, a pyrolytic conversion of wood, is used because per unit weight it has twice the calori c value of wood and, because of its lower moisture content, is signi cantly cheaper to transport from rural to urban areas. Charcoal making usually requires whole tree destruction. Using traditional charcoal making methods, it takes 10 sacks of wood to make one bag of charcoal, suggesting a signi cant energy subsidy from rural to urban areas. Biomass use creates both indoor pollution and contributes to outdoor air pollution.*

Wood and charcoal, as energy carriers, are at the bottom of what is called the *energy ladder*. Each ring of the ladder corresponds to a dominant fuel used by different income groups. The energy ladder, from bottom rung with the poorest income group, is wood, charcoal, kerosene, liquid petroleum gas (LPG) and electricity.

Movement up the ladder corresponds with greater energy efficiency (i.e., the fraction of energy reloaded from the

carrier that is actually turned into an energy service by the enduse device) and cleanliness. For example, cookstove efficiencies vary from 15% for woodfuel to 65% for gas. Moving up the energy ladder results in lower levels of carbon (C), sulfur (S) and particulate release. If significant numbers of people move up the ladder they will create an energy transition.

In theory, households choose energy carriers on the basis of income. Accessibility, convenience, controllability, cleanliness, efficiency and cost are the basis of choice. In the developing world, however, the transition by such choice is not straightforward. The energy carrier itself, its storage technology and the enduse devices themselves are subject to non-availability and breakdown. Kerosene can be limited because of an absence of foreign exchange to finance imports; LPG bottles may be in short supply; electrically operated machinery is frequently non-operational. Energy service security is important rather than income elasticity in determining energy choice. As a consequence, richer households tend to retain access to all energy-technology combinations rather than moving up the energy ladder.

The lack of movement up the energy ladder is compounded by the hidden subsidies on commercial energy, particularly electricity to urban households. These hidden subsidies mean that insufficient cash is raised by tariffs to allow equipment replacement in the power sector leading, in turn, to frequent system collapse. Energy insecurity blocks energy transition.

Parallel to the urban household energy problem is that of transport. Energy use for transportation grows rapidly with urbanization. As transport is predominantly oil-based, developing countries without oil resources face significant foreign exchange expenditures as transport accounts for more than 25% of all commercial energy in these countries.

Roads provide most transport. Essentially this is a private rather than a public solution leading to significant traffic congestion, and air pollution, as car ownership increases. Technical efficiency tends to be low in developing countries, because of older motor vehicles, although loading factors tend to be higher. Urbanization, economic growth and industrialization also require large increases in freight movement for access to markets.

Improvement in the transport system can be made by:

- moving to more efficient technologies;
- shifting to mass transit systems;
- improving the quality and mix of transport infrastructure.

Policies that encourage large shifts to public transit systems have been quite successful in Singapore and Manila, and reduce overall energy demand. Such shifts do, however, usually require changes in urban land-use planning.

Bioremediation

Bioremediation is the use of biological agents to control or remove pollutants and similar challenges to environmental health. Non-biological cleanup of pollution usually requires an intense physical and chemical attack on the pollutants (e.g., physically gathering oil spills or making them easier to handle by the use of detergents). The ecological hazards of the clean-up agents may be very serious, and clean-up costs are high. Bioremediation seeks to control pollution by using microbes and other biological agents to break down the pollutants to ecologically harmless substances.

The discovery of bacteria that can digest oil led to intensive research to select more active species or strains, with considerable success. A similar approach has been successful in improving the quality of wash water from mining operations, particularly those in which acidity from the rock results in the solution of toxic minerals that must then be removed. The detoxification of organic pollutants by fungi and bacteria has also been tried, and a variety of specific organisms have been discovered or developed by selection or genetic modification that attack specific chemicals (e.g., specific fungi have been found, such as the mushroom *Marasmiellus troyanus*, which can digest benzopyrene, a potent carcinogen from coal tar).

Not all bioremediation uses microorganisms. Mining or quarrying effluent may contain substantial dissolved toxic chemicals as well as suspended solids and silt. Environmental pollution from such sources has been effectively controlled by constructing an artificial swamp on the effluent watercourse, selecting plants (e.g., sphagnum and *Typha*) that have the capacity to sequester the toxic minerals or convert them to non-toxic derivatives, as well as filtering out the sediments. Some freshwater aquatic plants have been

investigated that detoxify mercury, and a selected alfalfa cultivar has been used to clean up soil nitrogen contamination from overfertilization, spills and livestock wastes.

Bioremediation has been applied successfully to sewage effluent, mining wastes, chlorinated solvents, pesticides, agricultural chemicals, oil, gasoline, creosote and a variety of specific organic chemicals including dry-cleaning wastes. However, the use of added microorganisms is not without some hazards. It has been necessary to monitor the environmental consequences of loading the ecosystem with foreign species, which may not simply disappear when the pollution has been cleared up. Similar problems have arisen in other types of biocontrol, such as the importation of foreign predators to control pests, when the predator does not always confine its attention only to the pest in question, but may attack other (sometimes desirable) species when the target organism has been reduced or eliminated. The more recent approach of taking advantage of naturally occurring organisms tends to avoid this problem and reduces environmental stress. However, some ecosystem disturbance usually occurs because it is often necessary to add nutrients to the polluted area to encourage the bioremedial agents. In balance, bioremediation has been a valuable and versatile approach to pollution control, and is usually much cheaper and less ecologically traumatic than other methods of clean-up.

Capacity, Assimilative

The empirically estimated capability of a natural ecosystem in a particular locale to accept and process wastes into an acceptable form has been called its *assimilative capacity* for those wastes. A century ago that concept was used mostly for the case of untreated human sewage that was led into owing waters. Immediately downstream of the sewage outlet, the natural decomposition processes resulted in offensive and harmful gases like ammonia and methane, and people were expected to stay away from such sites for their own good. The actual numerical estimate of the assimilative capacity, i.e., of how much sewage could safely be released into a particular spot in a particular river, required a prior decision on how far down the river such offensive products of decomposition would be tolerated by humans with other interests in those downstream parts of the river. If an important downstream use was threatened by pollution, then the assimilative capacity for pollution upstream would be set at a low level. The amount of sewage wastes that could be processed ecologically within a particular reach of a river was itself dependent on such factors as volume and rate of river ow, water temperature and whether the river had rapids or was owing only placidly. So the operative estimate of assimilative capacity would have to take such factors into account.

The notion of safety in such circumstances has interesting features. That the waters immediately downstream from an outfall of raw wastes were unsafe was clear. What rendered this regulatory approach safe was that the unsafe locales were zoned, formally or informally, to keep humans at a safe distance. Also, the numerical value of assimilative capacity that was formalized legally was not based on the worst possible scenario, say of some episodic event of excessive loading due to sewerage system malfunction or of unusually low river ow. At such times, downstream users were subjected to higher risks and were expected to ensure their own safety by compensating reactively, say by quickly stopping their own uses of the river until the risks abated. So the safety of downstream users depended on their prior understanding of those risks and then acting appropriately.

It is clear from the above that the concept of assimilative capacity provided a way to place some politically negotiated limit on the externalization of implicit costs by upstream sewage producers at the expense of downstream users of the river. As a river came to be used for more and different purposes, an early measure of assimilative capacity was generally found to be too generous, and then a new, lower assimilative capacity came to be formalized. Or a growing settlement might lead to increases in amount of sewage that would exceed the agreed assimilative capacity. Authorities responsible for sewage disposal then invented cost effective means to remove the more harmful components of sewage so as not to exceed the agreed assimilative capacity of the river. In developed countries such ratcheting down of the concentration of harmful substances released at the sewage outfall occurred by numerous steps. It is now feasible to process sewage technologically so that the ef uent has a quality appropriate for drinking water. If this is deemed to be cost effective, then it may be politically acceptable to assign the river in such a locale an assimilative capacity of zero with respect to sewage wastes. This may occur where politically powerful interests downstream

practice sensitive uses such as angling for sport fish that are particularly intolerant of ecological degradation of the river.

Setting assimilative capacity at zero is consistent with a rigorous interpretation of the *precautionary principle* in which a potential polluter pays the full costs of internalizing complete treatment of all the sewage.

We have used human sewage as an example for which a concept of assimilative capacity has long been used. But that concept was also used for industrial wastes such as gases, acids, bases, heavy metals, oils and complex chemicals that may be released into the waters, soils or atmosphere of a locale. To the extent that the relevant estimate of assimilative capacity was based on scientific understanding, as was usually expected, the amount of scientific information needed quickly became excessive. Part of the complication was due to the occurrence of adverse interactions amongst the ecological consequences of the assimilative processes of the different wastes that acted to exacerbate some of the separate adverse effects. It seldom happened that the adverse effects from one kind of waste resulted in the inactivation of the adverse effects of another kind of waste.

In developed countries this all came to be recognized in the 1960s, say by Sweden when that country triggered the first of the United Nations conferences on the environment in Stockholm in 1972. A complex systems approach, that eventually came to be called an ecosystem approach (*see* **Monitoring in Support of Policy: an Adaptive Ecosystem Approach**, Volume 4) in North America, then began to take the place of the excessively complicated linear approach of legal specification of different assimilative capacities for a large number of different wastes in an industrial city, say. The ecosystem approach led to an inference that a legal requirement for precaution was of critical importance.

As a transitional convention, the concept of assimilative capacity has come to be transformed into a concept of a temporary benchmark of *maximum permissible loading*. With an understanding that such a benchmark will likely be lowered by steps in the future toward a goal of zero discharge from current activities and virtual elimination of such wastes that remain in the environment from previous emissions. For example, a goal of zero discharge and virtual elimination was formalized for the Great Lakes by Canada and the US in 1978 with respect to particular hazardous contaminants; since then temporal benchmarks have been specified for some of these contaminants.

A goal of zero discharge into a nearby river, say, and immediate virtual elimination of all human and pet wastes from a city would likely be perceived as very unrealistic. Sewage infrastructure does malfunction occasionally, storms wash pet wastes from parks into streams, derelict parts of a city do not have sanitary conveniences, etc.

But a goal of zero discharge and virtual elimination, i.e., a legally specified assimilative capacity of zero, may be achievable for some excessively harmful kinds of wastes. These may include particularly hazardous forms of physical substances such as radionuclides, of chemical substances such as organohalides and of biological substances such as viruses and other pathogens. Infinitesimally small quantities of such substances can cause permanent harm to organisms, with initiation of disabilities at the time of fertilization or conception. Such effects include mutagenesis that involves harmful genetic mutations, carcinogenesis that triggers cancer, teratogenesis that causes permanent physical and physiological impairments, etc.

Clarification of what substances have properties for which a zero assimilative capacity is justified became the focus of international legal negotiations late in the 20th century. These negotiations have led to bans on the manufacture of some substances, such as persistent pesticides, that could only be used in ways that resulted in losses to the natural environment which, in effect, had already been assigned zero assimilative capacities for these substances.

Carbon, Sulfur, and Nitrogen: Trends in Global Emissions

see Trends in Global Emissions: Carbon, Sulfur, and Nitrogen (*Opening essay*, **Volume 3**)

Cattle Grazing: Impacts on Land Cover and Methane Emissions

Tapas Kumar Bandyopadhyay
Ministry of Environment and Forests, New Delhi, India

Methane (CH_4) is a naturally occurring greenhouse gas. It is generated due to bacterial action on organic material in anaerobic conditions. In nature, it is produced by the decay of organic materials in swamps.

Human activities are also a cause of the release of greenhouse gases into the atmosphere, accounting for about 70% of the total CH_4 emissions. Approximately 20% of total

CH_4 generation in the world is contributed by paddy fields. Livestock contributes about 16% of the total.

CH_4 is generated during the enteric fermentation process and from the anaerobic decomposition of animal wastes. It is estimated that domestic animals account for 94% of the total global CH_4 emissions by animals and human beings. Of that, cattle contribute 74% of animal emissions and sheep and goats contribute 13%.

PATHWAY OF METHANE EMISSIONS FROM ANIMAL SOURCES:

There are two sources of methane (CH_4) emissions from livestock (see Table 1):

1. From the digestive process,
2. from animal wastes.

CH_4 Emissions From the Digestive Process of Ruminants

The generation of CH_4 from the digestive processes of an animal depends upon the type of food intake, quality of food, and quantity of available food. Climatic conditions and seasonality affect CH_4 emissions. In a tropical country like India, higher CH_4 emissions from animals occur during the winter and rainy seasons. The age of an animal is also one of the most important factors for the production of CH_4.

Different types of microorganisms present in the digestive tracts of herbivorous animals are responsible for the production of CH_4 from digestive process of ruminants. Heterotrophic microorganisms decompose organic materials found in the feedlot.

There are three stages for decomposition of organic material in the digestive process of the ruminants. In the first stage the cellulosic materials are hydrolysed by cellulase into simple sugars (e.g., glucose and maltose). The soluble sugars are converted to simple organic acids by anaerobic and facultative bacteria (Figure 1). The organisms responsible for these transformations, called acid formers, function best in a range of pH 4.0 to 6.5. The major product of this step is acetic acid but propionic acid and butyric acid are also produced. Acetic acid is the most important substrate for the final reaction of the sequence, since 70% of the CH_4 produced has been shown to derive from that component. CH_4-producing bacteria (Methanogenes) convert acids to CH_4 and carbon dioxide under strict anaerobic conditions.

CH_4 Emissions From Animal Wastes

Animal wastes are generally composed of organic material and water. Under favorable environmental conditions, organic material present in animal wastes is decomposed by a group of organisms to become CH_4, carbon dioxide and other products. Primary microorganisms responsible for the decomposition of animal waste are heterotrophic bacteria. Heterotrophic bacteria can be classified as aerobic, anaerobic or facultative, depending on their need for oxygen.

Either an aerobic or an anaerobic process can break down the animal wastes. Under aerobic conditions, aerobic and facultative bacteria, using molecular oxygen, decompose the organic material. The end products of this process are carbon dioxide and stabilized organic material. Under anaerobic conditions, the animal wastes are decomposed to CH_4, carbon dioxide and stabilized organic material.

As already mentioned, organic materials in the animal waste are converted to CH_4 and carbon dioxide in three steps.

Step I: Hydrolysis by Enzymes

The first step is the enzymatic hydrolysis of animal waste. The enzyme cellulase is responsible for breaking down cellulose and starch into sugars such as glucose and maltose. Enzyme lipase breaks down lipids into smaller chain fatty acids and enzyme protease breaks down proteins into amino acids.

The extent of enzymatic reactions is controlled by the quantum of enzyme present in the system and the characteristics of the wastes and reaction conditions such as pH and temperature.

Step II: Formation of Small-chain Acids

The next step is the formation of small chain acids such as acetic acid (the main product at this stage), propionic acid and butyric acid.

$$2C_6H_{12}O_6 \text{ (glucose)} + 2H_2O \longrightarrow 2CH_3COOH \text{ (acetic acid (I))} + 2CO_2 + 4H_2 \text{ (hydrogen (II))}$$

Step III: Generation of CH_4

In this final stage, methanogenic bacteria convert acetic acid into CH_4 and carbon dioxide in strictly anaerobic conditions. This reaction process is very sensitive to temperature, pH and the composition of the substrate. The reaction can be expressed as:

$$\text{(I) } 2CH_3COOH \text{ (acetic acid)} \longrightarrow 2CH_4 \text{ (methane)} + 2CO_2 \text{ (carbon dioxide)}$$

$$\text{(II) } 4H_2 \text{ (hydrogen)} + CO_2 \text{ (carbon dioxide)} \longrightarrow CH_4 \text{ (methane)} + 2H_2O \text{ (water)}$$

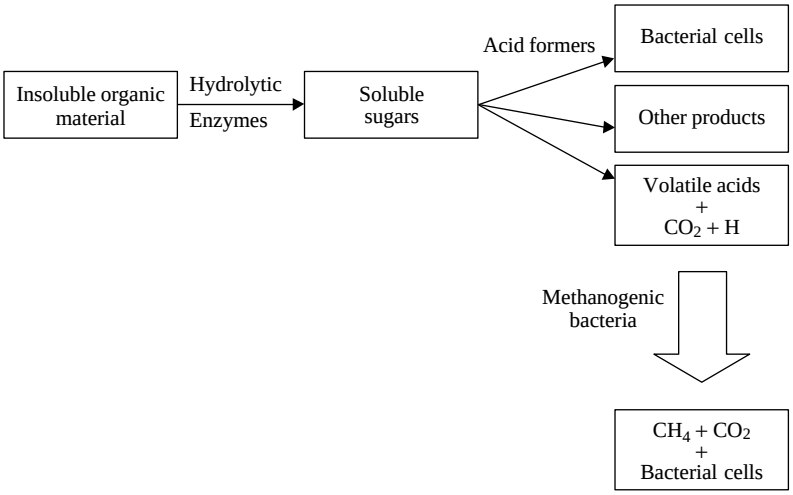

Figure 1 A simplified schematic of the overall mechanism of methane production in the digestive tract of ruminants

CATTLE GRAZING AND PASTORAL CHANGE

Cattle grazing refers to consumption of vegetation on a land area, especially grass, by cows, buffaloes, sheep and goats. The benefits of cattle raising include: the production of manure for fertilizer; the manufacture of products from leather, skin, bone, hair gut and meat; and the production of dairy products. Associated with cattle raising, there are a number of environmental evils such as the destruction of rain forests, competition with wild life for habitat, soil compaction and erosion from trampling, and pseudo problems such as CH_4 emissions from ruminant burping.

Pastures and CH_4 Emissions

There is no effective waste handling system for animal pastures. The manure from animals in these pastures is allowed to lie where it is. The animal waste dries out, reducing anaerobic decomposition. Chen *et al.* (1988) indicate that about 11% of the CH_4 producing potential of the manure is lost during the drying process. Hence, the extent of the CH_4-producing capacity in pastures is very low compared to liquid/slurry or anaerobic lagoons.

The United States Environmental Protection Agency (USEPA) estimates that CH_4 emissions from animal wastes in pasture total about 10.2 Tg year^{-1} out of which the highest contribution, 2.2 Tg year^{-1}, is from Latin American countries (USEPA, 1992) These estimates are only as good as the possibly inaccurate data on animal numbers, size, feed type, and CH_4 production potential on which they are based.

Tropical pastures able to produce year round even without irrigation are potentially more productive than those of sub-tropical or temperate regions. But due to soil moisture, tropical pastures become a better source of CH_4 emissions than temperate pastures.

Causes of Pastoral Change

A livestock management system plays an important role for the movement of animals to pastures. In most developed countries, livestock graze in confined fields or are reared indoors except in Australia and New Zealand where there is little confinement of livestock. In the developing countries in Latin America, Africa and Asia, most livestock graze on communal pastures.

The main causes of pastoral changes are:

1. clearing of tropical rain forests;
2. agricultural expansion into pastoral lands;
3. increased cropping;
4. overgrazing;
5. population pressure;
6. poor pasture management systems.

Present Global Status of Pastures

In developing countries and tropical regions traditionally unirrigated land is generally used for cattle grazing, forest development and dry-land crops.

In many parts of India, the area available for grazing has been reduced due to population pressure and conversion of grazing land into arable land. The pasture and other grazing areas need to be improved by controlled grazing through rotation and deferred, or intermittent, grazing systems.

The pastoral regions in China are located mainly in the Inner Mongolia autonomous region (IMAR), Xinjiang Uygur autonomous region and Qinghai province. At present, about 87 million ha, about one third of the useable grassland in the pastoral regions, are degraded. Every

year, another about 0.66 million ha of grassland become degraded (Liu, 1993). The causes of this trend can largely be attributed to the growth of the animal population, inadequate pasture development, and human population pressure.

In the northern Caspian Sea and Aral Sea region (Gael, 1988) the grazing areas in semi-desert areas are adversely affected due to excessive livestock grazing which has reduced the fodder available from 600 700 kg ha^{-1} to only 50 300 kg ha^{-1}. It has been suggested that the disappearing dominant species of these degraded pastures should be re-sown as soon as possible.

The farmers in Vietnam have traditionally exploited free natural grazing resources for the rearing of buffaloes and cattle (Froberg and Olsen, 1989). In the area in and around Vimu Phu province, the grazing lands are under stress due to the conversion of grazing land to agricultural cultivation on forest plantations or overgrazing.

In many parts of the Middle East and Africa, pastoral lands have become degraded through agricultural expansion into pastoral zones, the loss of critical dry season pasture, nationalization of pastoral resources and the collapse of the traditional common property resource management system (Johnson, 1993). In the Sahara-Sahel transition subzone rapid deserti cation is taking place as a result of excessive biotic pressure, the human population having increased by 226% and the animal population by 237% between 1970 and 1980 (Le Houerous, 1989). Recurrent drought and human population pressures have drastically reduced the density of pasture species in the Nigerian savannas (Igboanugo and Omijeh, 1990). The establishment of agro-pastoral farmers with plantings of eucalyptus has been suggested as a means of improving conditions in this zone.

In certain areas of Mexico intensive cattle grazing has resulted in deforestation. The increased moisture in pasture soils has lead them into becoming a source of CH_4 emission to the atmosphere.

In the State of Rondonia (Brazil), forest soils are a net sink of about 470 mg CH_4 m^{-1} while pastures are a net annual source of CH_4 from the soil of about 1 g CH_4 m^{-2}. The total annual pasture-related CH_4 release for the entire Brazilian Amazon increased from 0.8 Tg in 1970 to about 2.5 Tg in 1990 with a maximum release of 3.1 Tg in 1988. The average rate of increase in CH_4 emission from pasture was about 0.2 Tg CH_4 year^{-1} between 1975 and 1988. This represents between 12 and 14% of the global average rate of change in tropospheric CH_4 content for this time period (Flessa, 1996).

Increased cropping is one of the widely accepted causes of pasture degradation. In Australia, the primary production system used is not sustainable. About half of Victoria s crop and pasture lands are degraded or are at risk due to overgrazing and the failure to adopt an appropriate grazing and crop management system (Bird and Bicknell, 1992).

Strategies for Conservation of Pasture

To avoid irreparable damage to, and erosion of communal grazing lands, a systematic land use management system is needed. An integrated management scheme, ensuring an appropriate interrelation between arable pasture use, irrigation and reduction in grazing pressure is essential.

In China the following counter measures have been recommended to redress the imbalance: human population control and development of alternative income sources for the pastoral regions, pasture development through contracting of grazing land to individual households, joint household or production groups instead of the common grazing system, and a long-term pasture leasing system in a small number of counties with good natural, economic and social conditions in order to encourage investment in pasture development; and controlled stocking.

In order to restore damaged pastures, remedial measures like expansion of cropland, the exclusion of mobile herders from natural resource management schemes and subsidized livestock imports from developed countries must be changed or stopped. Sustainable practices are required for the conservation of pastures by proper pasture management.

LIVESTOCK POPULATIONS AND CURRENT TRENDS OF CH_4 EMISSION FROM LIVESTOCK

World-wide Cattle Population

In developed regions such as the United States, Canada and Europe, suf cient data are available to allow the populations of animals to be analyzed (Table 2). The regional percent of cattle population to total cattle population is given in Table 3.

In the developing regions of Africa and Asia livestock are not con ned. Most cattle there are multi-purpose and there are few specialized dairies. Most livestock graze on communal pastures and with little management of their wastes.

Animals produce signi cant quantities of CH_4 as part of their digestive processes. CH_4 emissions from all animals have been estimated by the IPCC to be between 60 and 100 Tg year^{-1}; accounting for about 16% of total global CH_4 emission from all source.

While the developing countries have a greater percentage of the cattle population than the developed countries, the yield of CH_4 from the digestive processes of cattle depends on the quality and amount of feed that each animal eats. The biggest eaters are dairy cows that receive three times their maintenance level feed. Hence, the average CH_4 production in the cattle of developed countries is also comparable with that in developing countries. This is due to the fact that a large portion in the cattle of developing countries is kept for draught purposes rather than for meat or milk. Such

developing country cattle are not fattened like dairy cows, and so produce less CH_4 per animal.

Trends of CH_4 Emission From Animal Wastes

A USEPA (1992) report estimates that global CH_4 emissions from animal wastes are about 28 Tg year^{-1}; with a range of about 20 to 35 Tg year^{-1}; about 6 to 10% of total annual anthropogenic emissions. Out of 28 Tg year^{-1}; three regions account for 78% of the total: Europe (Eastern and Western) with 11.4 Tg year^{-1}; (40%); Asia with 7.1 Tg year^{-1}; (25%) and North America with 4.2 Tg^{-1}; (15%) (Table 4).

METHODS FOR REDUCING GLOBAL CH_4 EMISSIONS

Technologies and practices exist that can reduce CH_4 emissions by 50 80% from animal waste management systems that are used for large numbers of confined animals.

In most developing countries like India, Bangladesh and Sri Lanka, about 95% of cattle are confined in small animal holdings and only 5% of the total cattle are managed by organized agribusiness. So, in order to reduce CH_4 emissions from animal wastes, animal wastes need to be collected and treated for recovery of CH_4. The recovered CH_4 (bio-gas) can be used as an alternative energy source to heat and light houses.

Reduction of CH_4 emissions can be achieved by modifying the composition of the diet. Most of the cattle in developing countries survive on grass and rice/wheat straw. Hence, it is necessary to find out the exact feed combination that will produce the least CH_4.

Other approaches for reducing CH_4 emission from digestive process of ruminants include: the elimination of protozoa in the ruminants will results in lower CH_4 emissions and may enhance animal performance, improved ruminant performance through the use of locally produced feed supplements and the improvement of fiber digestion efficiency and inhibition of enzyme activity of methanogens through a biotechnological approach.

Cereal Cultivation (Agriculture, Extensive)

William J Carlyle
University of Winnipeg, Winnipeg, Canada

Extensive cereal cultivation, the most recently developed of the world's main agricultural systems, is found largely in areas of former temperate grasslands. The emphasis from the beginning of cultivation has been on wheat production. The system was initially made possible by the use of machinery, and adaptations of crops and cropping practices to suit sub-humid and semi-arid environments. The adoption of ever larger-scale machinery has led to increased farm sizes, especially since World War II.

The conversion of tens of millions of ha of perennial grasslands to cropland is the clear environmental impact of cereal cultivation. Considerable controversy surrounds other impacts. Soil organic matter has decreased and soil erosion and soil salinity have increased since original cultivation. However, the reduction of summerfallow since 1970 and more recent reductions in tillage have slowed rates of organic matter loss, erosion, and salinity.

Tree planting in some areas to ameliorate the local climate has brought only minor bene ts. Shelterbelts around farmsteads or farm villages have, however, provided beauty, protection from the wind and sun, and a relief from uninterrupted horizons. Field shelterbelts are not extensive overall, but where they have been established, they also provide relief from horizontal horizons, and they help reduce soil erosion by wind.

Climate changes mainly due to urban and industrial activities elsewhere have already begun and are continuing in the extensive cereal districts. It is generally expected that average temperatures will increase in these districts, but there is uncertainty about changes in precipitation. A rise in temperature, without commensurate increases in precipitation and other mitigating measures, would reduce soil organic matter, add carbon dioxide to the atmosphere, and reduce crop yields. If, however, there is an increase of atmospheric carbon dioxide together with increases in temperature, precipitation, and fertilizer use, as well as a reduction in tillage and fallow, signi cant increases in yield could occur.

INTRODUCTION

Extensive cereal cultivation today occupies areas in the mid-latitudes, which were, until recently, mainly temperate grasslands (Figure 1). Cereal cultivation did not begin to replace nomadic herding and ranching in these areas until the late 1800s. By about the 1930s, the perennial grasslands had been largely ploughed up and sown to annual grasses, especially wheat, in the largest short-term expansion of cropland in history.

There are several reasons why crop farming was so long delayed in the temperate grasslands. The climate is sub-humid to semi-arid, with an annual precipitation of about 250 500 mm, but higher amounts occur in such areas as the humid parts of the Argentine Pampas (Figure 1). Moreover, the precipitation is variable from year to year, and periodic droughts occur. In North America, at least, the lack of trees was taken to be an indication that the grasslands were too dry and the soil not fertile enough for widespread crop agriculture (Grigg, 1974). In the Pampas, the estanicia (large estate) owners favored cattle and sheep, and they were generally unwilling to become crop farmers. Perhaps most important, however, was the difficulty of clearing the tough prairie sod by human and animal power with traditional tools (James, 1951). Other important factors were the lack of railways to export the crops and bring in necessary equipment and supplies, including lumber, fuel, and fencing, and the lack of demand for cereal crops on the scale that the grasslands might produce them. An exception is that the steppes north of the Black Sea were partially cleared between the late 1700s and late 1800s by domestic animals and human muscle power in conditions of serfdom and virtual slavery (James, 1951).

CLEARING OF THE GRASSLANDS

The conditions that delayed the development of the grasslands into cropping areas began to change in the late 1800s. Industrialization, urbanization, population growth, and increasing incomes in Northwestern Europe and Eastern North America led to an increasing demand for wheat.

Implements such as the self-scouring steel plough, the binder and reaper, the steam powered thresher, barbed wire for fencing, and steel windmills to draw up water became available in the American Great Plains and Canadian Prairies. Help in establishing cereal cultivation in Australia came from the stripper for harvesting, the stump-jump plough for cultivating among eucalyptus roots in newly cleared land, and a harvester suitable for local conditions. In a similar manner, steel ploughs, reapers, and steam threshers were introduced to the Pampas (Grigg, 1974). Immigrants from Spain and Italy, who became crop-share tenants on the estancias, planted most of the wheat in the Pampas. They would sow wheat for several years, after which the land was sown to alfalfa for cattle feed, and the tenants then moved to other parts of the same estancia or to other estancias to repeat the process (Grigg, 1974). In the Russian steppes east of the Black Sea, plentiful and cheap labor allowed clearing without the degree of

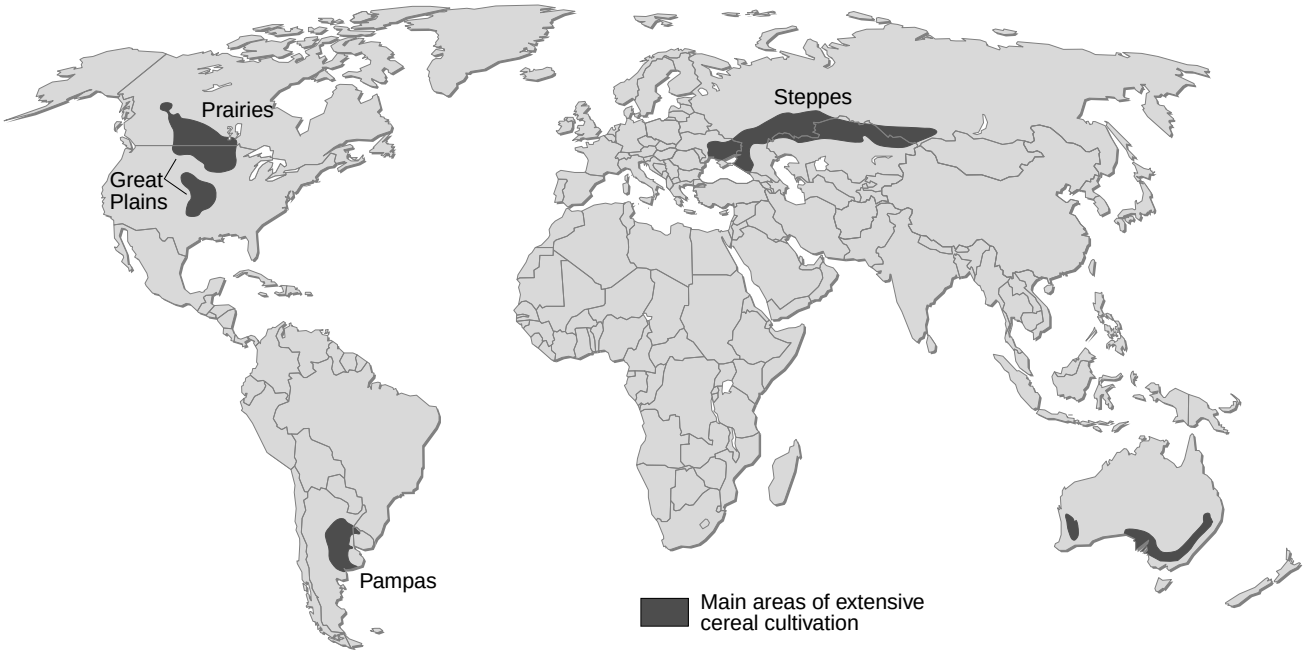

Figure 1 Main areas of extensive cereal cultivation. Excluded here are several smaller areas of extensive cereal cultivation, such as the Paris Basin and the Palouse region of Northwest continental United States of America

mechanization used elsewhere in the temperate grasslands, although mechanization was later adopted by the Soviets.

Strains of wheat were developed which were better suited to the climates of the grasslands, and summer fallowing, i.e., leaving the land without a crop for an entire growing season, was developed to accumulate moisture in semi-arid areas.

The clearing of the grasslands would probably not have occurred as quickly and expansively as it did, however, were it not for the fact that the late 1800s were the railway age. Railways were crucial both to bring in settlers and supplies and to transport cereals to distant markets inexpensively. The replacement of wooden sailing ships by iron steamships also expedited grain exports.

These developments led to the rapid expansion of cereal cultivation into the grasslands, leaving the ranchers and herders in possession of only the drier margins by the end of the main clearing period, which lasted to about 1930 (Figure 2).

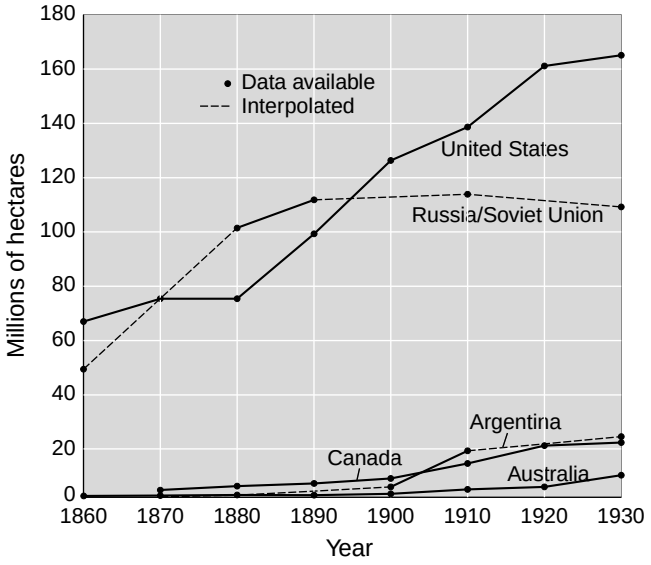

Figure 2 Trends in cropland, 1870 to 1930. Much of the increase in cropland occurred in areas of extensive cereal cultivation

RECENT DEVELOPMENTS

Since the 1930s, and especially since World War II, farming in the former grasslands has become increasingly mechanized and extensive. Combine harvesters, larger and more powerful tractors, and a wide range of other labor saving equipment, together with at land suited to large-scale machinery (James, 1951), have allowed farms to rapidly expand in size.

In the Great Plains and Prairies, where original homesteads were an already sizeable 65 ha, grain farms now are hundreds or thousands of ha in extent. In the Australian grain districts, original farm sizes of 120 160 ha have increased to 500 1500 ha, and even larger. The Pampas began with very large estancias and they have remained large (Rudolph, 1985), although some

estates have been subdivided into smaller owner-occupied holdings. Individual family farms have never been common in the steppelands of Russia, Ukraine, or Kazakhstan. The farm village or *mir* was the traditional farm unit in Old Russia, and these were replaced in the Soviet Union by collectives (*kholkhozes*) and state farms (*sovkhozes*), beginning in the early years of the Stalin era. Sizes of collectives varied, with about 2500 4000 ha being a representative figure by the 1960s. State farms were generally considerably larger.

Beginning in the 1950s, the Virgin and Idle Lands Program was launched by the Soviets. It involved the ploughing up of some 30 40 million ha of land in the drier southern margin of the steppes, largely in Kazakh Soviet Socialist Republic, where annual rainfall decreases to 250 mm (Grigg, 1974). This expansion was accomplished mainly on highly mechanized and very large state farms, which averaged more than 60 000 ha each (Hooson, 1966). Since the collapse of the Soviet Union, the whole system has fallen into disarray, but to date there appear to be very few individual family farms.

In Australia, the establishment of wheat farms at first pushed sheep onto the dry margins. Since the 1930s, however, sheep have been integrated with wheat production. Clover and other forage crops, grown in rotation with wheat, feed the lambs and fix nitrogen in the soil, while the sheep add manure fertilizer to the fields. In addition, trace elements such as copper and molybdenum, originally generally deficient in the grain belt soils, have been added to the soil along with nitrogen and superphosphates, leading to increased yields (Bambrick, 1994).

Wheat is still the dominant crop in all the main areas of extensive cereal cultivation. In the more moist areas, however, cropping has become more diversified, with extensive sowing of barley, canola (rapeseed), sorghum, alfalfa, and other less significant crops. The increase in livestock numbers means that some areas, notably Central and Eastern Ukraine, are now more aptly described as mixed farming regions than as extensive cereal cropping districts.

In all areas of extensive cereal cultivation, crop yields, here exemplified by wheat, have risen substantially in recent years, except in the former Soviet Union (Table 1). This increase has occurred for various reasons, but the increasing use of manufactured fertilizers is a main cause.

EXTENSIVE CEREAL CULTIVATION AND THE ENVIRONMENT

Although extensive cereal cultivation is of recent origin, it has affected the environment in many ways. Chief among these, besides the conversion of tens of millions of ha of natural grassland to crops, are loss of soil organic matter, soil erosion by wind and water, spread of soil salinity, and the planting of trees and shrubs around farmsteads and on fields. The possible effects of anthropogenic alterations of the climate on cereal cultivation will also be examined.

Soil Organic Matter

Under natural conditions, soil organic matter in the temperate grasslands was high, varying from about 3 5% in the drier districts to as high as 10% in the moister areas. However, in Australia, where eucalyptus, shrubs, and grass were the natural vegetation in the areas of extensive cereal cultivation, organic matter levels were in places as low as 1 2%. Converting the grassland to cereal crops led to a decline in organic matter because part of the biomass was removed with the harvest or burned, cultivation accelerated the rate of destruction of organic matter, and there was loss of organic matter through erosion. The practice of summer fallowing further contributed to the loss of organic matter because no crop was sown in the fallow year, hence reducing primary biomass production. Frequent tillage to control weeds during the fallow increased the rates of decomposition of organic matter and soil erosion, and some of the

moisture accumulated during the fallow tended to leach soluble nitrate nitrogen below the rooting zone (Rennie, 1989).

The loss of soil organic matter is considered to be potentially, if not already, serious for several reasons. Organic matter contains many of the nutrients needed for cereal crop growth, notably nitrogen. It improves soil aggregation and tilth, provides a rooting zone for crops, and is important for moisture-holding capacity.

How much soil organic matter has declined is, however, debatable. It is generally agreed that there were rapid losses for about 20 years after initial clearing, then a leveling off to a slower decline. In the Canadian Prairies, there was much concern in the 1970s and 1980s when estimates of soil organic loss since clearing ranged from 50 70% (Gregorich *et al.*, 1995; Rennie and Ellis, undated). These estimates appear to be based on a cropping sequence in which half the arable land was left in summer fallow each year i.e., a grain crop one year followed by fallow the next. A more recent study, in contrast, places the losses of soil organic matter in the order of 15 30% (Gregorich *et al.*, 1995). This study bases its estimate on losses of organic matter since initial cultivation on uneroded soils which, in the Prairies, means mainly soils which have been continuously cropped since clearing, that is, they have not been summer fallowed (E Gregorich, personal communication, February 7, 2000). This estimate appears to be low because until about 1970, summer fallow was practiced throughout the Prairies (Carlyle, 1997).

Whatever the actual losses are, it is apparent that several measures are now reducing the rate of loss of soil organic matter in the Prairies. Perhaps most importantly, between 1971 and 1996, summer fallow decreased in the region from 10.6 6.2 million ha (Carlyle, 1997). Also, even where summer fallow is still practiced, tillage operations to kill weeds during the fallow period have been reduced or eliminated altogether over large areas by using herbicides. Thus, in 1996, herbicides together with less tillage than on conventional fallow were used to control weeds on 37% of fallowed land, and, on 9% of the fallow, tillage was eliminated altogether by using only herbicides to control weeds (Statistics Canada, 1998). Reduced tillage on fallow reduces the rate of loss of soil organic matter by slowing down microbial action and erosion (Janzen *et al.*, 1998). In addition, crop yields have been increasing, partly through the use of manufactured fertilizers, while the decay of a greater biomass increases total organic matter (Table 1). Furthermore, farmers in the region are increasingly adopting reduced or no tillage on the cropped land, practices which leave more plant debris on the soil, thereby reducing erosion and adding to the pool of organic matter compared to traditional tillage methods (Table 2, Figures 3 and 4).

Higher yields, reduced tillage, and a decline in summerfallow have also taken place on the US Great Plains, which should stabilize or increase soil organic matter there (Table 1). A Mediterranean climate with cool, wet winters and hot, dry summers characterizes the extensive cereal zones of Western Australia and the southern part of Southeastern Australia. In these zones, cereals are sown in the autumn (May) to take advantage of the winter rainfall, and are harvested in late spring (November), making the practice of fallowing for additional moisture unnecessary or ineffectual because of very high evaporation rates during the hot summers. Fallow is, however, practiced in the northern districts of Southeastern Australia, where most rainfall

occurs during the summer. Clovers, sheep, and manufactured fertilizers have helped raise cereal crop yields and soil organic matter. In addition, farmers have been rapidly adopting reduced tillage and no tillage, which not only reduce loss of soil organic matter, but also conserve moisture. In Western Australia, for example, it is estimated that each cultivation may cause 2 cm of extra evaporation. In the past five years, up to 400 t ha^{-1} of clay have been added to sandy, water repellent, soils in the extensive cereal districts, which increases yields and hence soil organic matter because of increased soil moisture retention. These measures have resulted, in places, in an increase of soil organic matter since initial cultivation (Crabtree, personal communication, January, 2000).

The loss of soil organic matter in the Pampas appears to be less than in other areas of extensive cereal cultivation. Wheat is generally sown for several years, followed by alfalfa (lucerne) for five or more years, which protects and builds up organic matter in the soil. The author could find no current information on soil organic matter levels in extensive cereal districts of the former Soviet Union. It is, though, apparent that yields of wheat have risen little in recent years, which suggests that methods of tillage, fallowing, and fertilizer use have changed little, at least in the main wheat belt east of the Black Sea in the Russian Federation and Kazakhstan (Table 1). It would therefore seem that there have been few corrective measures to curtail losses of soil organic matter.

Soil Erosion

Estimates of the causes, amounts, and costs of soil erosion in areas of extensive cereal cultivation are even more divergent than those for losses of soil organic matter. For example, soil drifting and dust storms in the Great Plains and Prairies during the 1930s (Figure 5) have commonly

Figure 5 Soil erosion and drifting near Cadillac, Saskatchewan, in the 1930s. (Reproduced with permission of the Prairie Farm Rehabilitation Administration, Regina, Saskatchewan, file photograph 32227)

been ascribed to inappropriate farming techniques exacerbated by drought (Herrington *et al.*, 1997). Malin (1956), however, points out that severe dust storms occurred in the Plains in 1830, long before the land was cultivated, and he states that No more brazen falsehood was ever perpetrated upon a gullible public than the allegation that the dust storms of the 1930s were *caused* by the plow that broke the Plains (Italics Malin s).

More recently, several studies estimated the costs of soil erosion in the Canadian Prairies. These estimates varied from $369 million (Cdn.) per year (Sparrow, 1984) to $430 million (Cdn.) annually (Smith, 1986). Smith (1986) goes further in giving a figure of $1.011 billion annually for losses on the Prairies from all types of soil degradation, with organic matter losses and salinity costing $314 million and $212 million, respectively. These figures refer only to the on-farm costs of degradation; they do not include off-farm damages caused by soil from farms such as silting of reservoirs, damages to peoples health, and infilling of ditches.

In sharp contrast, in studies of soil erosion in the US Great Plains, where conditions are similar to the Prairies, soil erosion was not a major factor.

Alt and Putnam (1989) estimated the amount of wind and water erosion in the Great Plains by focusing on areas where soil erosion exceeded soil formation. They estimated that after 100 years of erosion at 1982 rates, there would be, in the 100th year, a loss of only 1.4% in crop yields in the Northern Plains and 2.6% in the Southern Plains. Moreover, they estimated that about 75% of the cropland in the Great Plains would, in the 100th year, lose less than 2% of its yield from erosion, and 90 95% would lose less than 8%. Crosson and Stout (1983) estimated that losses in mean yields of wheat due to water erosion in the Great Plains for the years 1950 1980 were only 1%. More generally, Crosson and Rosenberg (1989) claimed that The US is the only country in the world with reasonably accurate and comprehensive estimates of soil erosion and its effects .

Recent studies of soil erosion, and soil degradation generally, on the Canadian Prairies suggest that earlier figures were overestimates (Acton and Gregorich, 1995). Wall *et al.* (1995) claim that, in 1991, less than 5% of the cultivated land was at a high to severe risk of wind erosion, and that some 95% of the cultivated land was at a tolerable risk of water erosion. Furthermore, they estimate that the risk of wind and water erosion declined on the Prairies between 1981 and 1991, mainly because of increasing use of reduced tillage and no tillage, and also because of a reduction in summerfallow, a cropping practice (Figure 6). They also state that it is to be expected that the risk of wind erosion had been further reduced by 5 10% between 1991 and 1995. Lerohl and van Kooten (1995) conclude that most of the 1980s soil erosion figures in the Prairies were overestimates, often grossly so, and that soil erosion of farmland did not cause much damage in the region, either on or off the farm.

The disagreements about the severity of erosion in the Prairies and Great Plains, and probably in areas of extensive cereal cultivation elsewhere, appear to arise for several reasons. The high estimates are generally based on the assumption, usually unstated, that the eroded soil is lost forever to agriculture (Lerohl, 1991). They seem, furthermore, to extrapolate dry conditions, such as those of the 1930s and 1980s, into the future. This is of particular importance because wind erosion is the main type of soil erosion in the Prairies, and it appears to be more damaging in dry years (Wheaton and Wittrock, 1991).

The lower estimates consider such factors as rates of soil formation, and the re-deposition of a considerable proportion of the soil moved by wind in particular, but also by water, on farmland elsewhere in the region (Crosson and Stout, 1983; Lerohl and van Kooten, 1995).

Although the estimates of soil erosion vary considerably, most writers urge continuing assessment of soil erosion and remedial measures to reduce it. Although the net effects of soil erosion over large areas may not be severe, individual farmers have much to lose from local erosion. Government agencies are therefore urged to switch from blanket regional measures to actions targeting specific sites and soil types where erosion is above acceptable levels.

Soil Salinity

Soil salinity is a problem in the main areas of extensive cereal cultivation because of the climate and farming practices. In situations where there is water surplus to crop needs, water soluble salts, mainly sulfates, chlorides, carbonates, and bicarbonates of calcium, magnesium, and sodium, move downwards to the water table. These salts can move downslope to discharge areas, and if evaporation is in excess of precipitation (a condition that is common in areas of extensive cereal cultivation), the salts are brought to the surface by capillary action. High levels of salinity have the same effect as drought by making water less available for uptake by plant roots and, if the soil is extremely saline, it will cause water to be drawn out of the plant. As a result, crop yields are lowered or the land is rendered unsuitable for cropping altogether.

Salinity occurs naturally in areas of extensive cereal cultivation (*primary salinity*), but it has become more widespread and severe since the clearing of the grasslands (*secondary salinity*). One reason is that annual cereal crops take up less water than perennial grasslands, and hence more water percolates below the rooting zone than it did before clearing. This raises the water table. The higher water table results in more water being brought to the surface in discharge areas, where it evaporates leaving the salts in the soil (Sparrow, 1984). In areas where it is frequently used, summer fallow appears to be the main cause of the spread of soil salinity. Only about 25% of the moisture accumulated during the fallow is stored in the soil; the remainder either runs off, evaporates, or enters the water table. The latter contributes to an increase in soil salinity. Even without fallowing, sandy soils, especially sandy water repellent soils, cause salinity to spread because of their low water-holding capacity.

As for losses of soil organic matter and soil erosion, estimates of the severity and costs of human-induced (secondary) soil salinity vary. One reason is that most or all of soil salinity has sometimes been attributed to human actions, that is, the role of primary salinity is not given much, if any, consideration. Another is that projections of soil degradation by secondary salinity have been based on a few plot-scale experiments rather than on widespread studies. Examination of soil salinity in the Canadian Prairies illustrates these comments.

One study estimated that 2.3 million ha in the Prairies were affected by soil salinity in the early 1980s, although there was no breakdown for secondary as opposed to primary salinity (Sparrow, 1984). This study claimed that summer fallow was the main cause of secondary salinity, and that secondary salinity was being extended at a rate of 10% per year. The annual costs due to decreases in crop production because of soil salinity were estimated to be at least $260 million (Cdn.). Another study, also published in 1984, focused on secondary salinity (Anderson and Knapik, 1984). It also pointed to summer fallow as the main cause of secondary salinity, but claimed that the often used 10% per year increase in such salinity was an overestimate, and used instead of a 1% per year figure. The cost of secondary salinity because of decreased crop production on the estimated one million ha of land affected in 1984 was estimated to be $105 million (Cdn.), with the annual cost rising to $128 million by 2008. A third study done in the 1980s claimed that secondary salinity affected 2.2 million ha of land in the Prairies. It estimated that secondary salinity was spreading at a rate of 10% per year, and cost an increased loss of $25.8 million (Cdn.) annually from lost crop production, which would amount to $4.42 billion (Cdn.) over the period 1983 2000. As with the other studies, summer fallow was deemed to be the main cause of secondary salinity (PFRA, 1982). Yet another study placed the annual cost of soil salinity, apparently both primary and secondary, at $212 million (Cdn.), with fallow again being the main cause of secondary salinity (Smith, 1986).

A recent study of soil salinity in the Canadian Prairies claims to have made the first attempt to describe salinity in the region in a standard way and to provide a baseline for further measurements (Eilers *et al.*, 1995). This study provides maps and tables showing the amount of farmland in the Prairies affected by various degrees of salinity; low (less than 1% of the land affected), moderate (1 15% of the land affected), and high (more than 15% of the land affected). For the Prairies as a whole, 62% of the total farmland was found to have a low degree of salinity, 36% had a moderate degree, and only 2% had a high degree. Moreover, most farmland in the region was assessed to be at little to no risk of becoming more saline under cropping practices used in 1991, and it was stated that the decrease of summer fallow in recent years had decreased the risk of secondary salinity from this practice.

Experimental plots have shown that leaving strips of tall stubble (grain stalks) at harvest traps more snow than short stubble, and leads to a more even distribution of snow throughout fields. This reduces ponding of water when the snow melts, and reduces the risk of salinization. Furthermore, the additional snowmelt has been shown to increase crop yields. Widespread adoption of tall stubble strips would therefore be beneficial in areas of extensive cereal cultivation in the Northern Hemisphere where snow is a normal winter occurrence.

Soil salinity appears not to be a major problem in the Argentine Pampas, mainly because the alfalfa sown in rotation with wheat allows very little water to seep downwards into the water table (Eilers *et al.*, 1995). It does affect cropland in the US Great Plains, but should be less than it was mainly because of a decline in summer fallow. Salinity is a major problem in areas of sandy water repellent soils in the extensive cereal districts of Australia, and it is expected to

become worse (Crabtree, personal communication, January, 2000). Mitigating measures include adding clay to the soil to reduce seepage into the water table. No current data could be found regarding soil salinity in the former Soviet Union, but it has been a problem in the past, especially in the area east of the Black Sea (*see* Salinity and Agriculture, Volume 3).

Planting of Trees

There were trees mixed with grass in parts of the temperate grasslands before cultivation, for example in the northern part of the Canadian Prairies (parkland), the Eurasian steppes (wooded steppe), and in Australia (eucalyptus, shrubs, and grass). Over most of the pre-cultivation landscape, however, trees were found only along the water courses, leaving vast expanses of treeless grassland. As cropland farmers entered the grasslands in the late 1800s, tree plantings began and have continued to the present day. These plantings have altered the landscape and microclimate of the areas of extensive cereal cultivation, and hence are part of the process of environmental change. However, they are not, strictly speaking, related to extensive cereal

Box 1 Shelterbelts

SHELTERBELTS AND CLIMATE CHANGE

Proposals for tree plantings in the US Great Plains and Canadian Prairies began during the pioneer settlement period of the late 1800s. In the Great Plains, the eminent geologist, F V Hadyn, suggested that large-scale tree plantings should be undertaken because such plantings would lead to a moister climate and improve soil fertility (Rees, 1988). Dean Bessey of the University of Nebraska made similar claims, stating that the Plains were dry because they were treeless (Rees, 1988). In Canada, Professor William Brown suggested that trees be planted in the Prairies because ''A peopled agricultural country without trees is an impossibility'' (Brown, 1884, cited by Rees, 1988). In the late 1800s, it was believed that trees would ameliorate the climate of the Ukrainian steppe grasslands (Rees, 1988).

This concept was revived in the US and in the Soviet Union during the 1900s. During the 1930s, a period of extreme drought in the Great Plains, some 30 000 km of tree belts were planted along the 100th meridian, but with little long-term success because of low survival rates (Burke, 1956). It is, however, in the Soviet Union that the most ambitious plan to modify climate by planting trees was undertaken as part of a wider project known as Stalin's Plan for Reforming Nature (Alisov *et al.*, 1952, cited by Thornthwaite, 1956).

The afforestation part of Stalin's plan, announced in 1948, involved the planting of six million ha of forest strips to protect 120 million ha of farmland on the steppes north of the Black and Caspian Seas (Burke, 1956). These strips, it was claimed, would reduce the loss of snow from farmland by curtailing Arctic winds from Siberia (burani) in winter. In summer, evaporation would be reduced by protecting the cropland from the full force of hot, dry winds (suxovei) from the arid lands of South Central Russia (Burke, 1956). Mitigating the effects of both these winds would, it was asserted, result in increased soil moisture and higher grain yields. Moreover, the Soviets thought that not just the microclimate but the macroclimate of the region could be modified by afforestation. A progress report in 1951 stated that two million ha had been planted, although no mention was made of survival rates (Burke, 1956).

Rees (1988), Thornthwaite (1956), and Burke (1956) all were very skeptical of the efficacy of these plantings in changing the climate for the better. As Rees (1988) put it ''Trees do reduce rates of evaporation, and so conserve moisture, but the plains were dry not because they were treeless but treeless because they were dry.'' Thornthwaite (1956) was confident that the Soviet plan would effect only trivial changes in climate. Burke (1956) claimed that the consensus was ''that such speculation (changing the climate by planting trees) is largely nonsense.''

SHELTERBELTS FOR BEAUTIFICATION AND EROSION CONTROL

Trees were, however, planted in the areas of extensive cereal cultivation for more practical reasons. Shelterbelts around farmsteads, especially if they contained flowering species, beautified surroundings in summer and, if they included coniferous species, did so in winter by adding green to the landscape (Rees, 1988). Such belts also shielded the farmstead from the sun and wind, shut out the endless space of the farmland beyond, and, when mature, could be used for firewood.

The planting of farm shelterbelts took on an almost religious fervor in the United States after the first Arbor Day, a day set aside and dedicated to tree plantings, was declared in Nebraska in 1872. Arbor Day subsequently spread throughout the US and into Canada.

The planting of field shelterbelts to reduce soil erosion by wind began in both the Great Plains and Prairies during the dry 1930s. In Canada, a federal government agency, the Prairie Farm Rehabilitation Administration (PFRA), undertook the distribution of seedlings to farmers. Several areas of farmland highly susceptible to wind erosion were targeted for intensive plantings (Wall *et al.*, 1995). One such project was near Conquest, Saskatchewan (Figure 7). Similar programs have been undertaken in the areas of extensive cereal cultivation in Australia.

Although not known at the time when most farm and field shelterbelts were planted, it is now recognized that they store significant amounts of carbon, and hence reduce emissions of carbon dioxide (CO_2) into the atmosphere (Janzen *et al.*, 1998; Johnston *et al.*, 2000). For example, the PFRA estimates that typical shelterbelt trees contain 162–544 kg C, and that shelterbelt shrubs contain up to 52 tones C km^{-1}.

Box 1 (*continued*)

Figure 7 Field and farm shelterbelts near Conquest, Saskatchewan. (Reproduced by permission of the Prairie Farm Rehabilitation Administration Shelterbelt Centre, Indian Head, Saskatchewan, CAI–76–210A)

cultivation, and therefore they will be separately examined (see Box 1 on shelterbelts).

Climate Change

It is generally agreed that the global atmospheric concentration of greenhouse gases has increased because of human activities. The viewpoint taken here is that it is probable that human activities have contributed and will continue to contribute to climate change, although the precise contribution of humans is not now known.

Whatever the impact of human activities on climate change, it is certain that activities associated with extensive cereal cultivation have not had and will not have a signi cant impact on climate change. Climate change would, however, have impacts on this type of agriculture.

It is generally agreed that global warming has occurred in the main areas of extensive cereal cultivation, and that this trend will continue, and that the greatest warming will occur in the Northern Hemisphere. For example, a recent study estimated that the average annual mean temperature in the Canadian Prairies had increased by 0•9 °C between 1895 and 1996, and that all three global circulation models predicted further increases in mean temperatures in all seasons (Herrington *et al.*, 1997).

If this warming trend continues, crop types and yields could change, depending on the amounts of precipitation and available soil moisture. A decrease in precipitation, which some models predict, would lead to decreased crop yields and a decrease in soil organic matter because of less primary biomass and because soil organic matter varies inversely with temperature (Breymeyer *et al.*, 1996). On the other hand, conservation tillage methods and reduction in summer fallow, trends apparent in many areas of extensive cereal cultivation, could counteract these losses of soil organic matter (Janzen *et al.*, 1998; Breymeyer *et al.*, 1996). Similar results could occur if precipitation increased insuf ciently to offset the higher evaporation rates caused by higher temperatures.

If, however, precipitation increased to the degree that available soil moisture also increased, crop yields would go up, and it might be possible to grow more heat- and moisture-demanding crops such as maize. It should be noted, too, that an increase of carbon dioxide in the atmosphere, providing there is suf cient water, would itself increase yields because carbon dioxide promotes plant growth.

It could well happen that different climatic changes would occur in different parts of even a single extensive cereal zone. This has, in fact, been predicted for different parts of the Canadian Prairies.

McGinn *et al.* (1999) used two climate change scenarios developed from the Canadian Climate Change Global Circulation Model to predict changes in crop yields in Alberta. One scenario involved warming and increased soil moisture, and it resulted in substantial increases in yield; 34% for wheat and 47% for canola. The other scenario involved warming only, which would mean a decrease in overall soil moisture. But, even so, yields were predicted to increase probably because earlier spring seeding would allow more ef cient use of spring precipitation, and more rapid maturity because of higher temperatures would decrease the total amount of water required for plant growth.

In contrast, Raddatz and Shaykewich (1997) predicted a decrease in crop yields on unirrigated land in the eastern part of the Canadian Prairies because of decreased overall evapotranspiration, which would occur because warmer summer temperatures would hasten crop maturity.

CONCLUSIONS

Extensive cereal cultivation has contributed to global environmental change and will continue to do so in the future. It has caused losses in soil organic matter, soil erosion, and the spread of soil salinity. Changes in cropping and cultivation practices, notably a decline in summer fallow and reduced tillage, have reduced soil degradation from these sources. Climate change has taken place in these areas and is expected to continue. Much uncertainty surrounds the effects of climate change on the yields and types of crops. Shelterbelts have been planted in areas of extensive cereal cultivation, and they locally reduce wind erosion and alter the climate, as well as beautify surroundings.

Changes in World Marine Fish Stocks

Ian Douglas
University of Manchester, Manchester, UK

An analysis by the Food and Agriculture Organization (FAO) of the United Nations, based on sh harvest records from 1950 to 1994, found that 35% of the most important commercial sh stocks showed a pattern of declining yields. Another 25% showed steady yields but were being shed at their biological limit and are vulnerable to declines if sh- ing levels increase (United Nations Food and Agriculture Organization (FAO), 1997a). The harvest of overexploited sh stocks fell 40%, from 14 million metric tons in 1985 to eight million metric tons in 1994. These numbers masked more precipitous drops in certain sh stocks such as Atlantic cod, haddock, and red sh, which had all but disappeared in some areas of the North Atlantic (Figure 1).

Some 80 million metric tons of sh are presently available for direct human consumption annually. The FAO expects demand to increase to 110 to 120 million metric tons by 2010 as the world population increases. Such a demand could be satis ed only if aquaculture production doubled and over- shing was brought under control so that ocean sh stocks could recover. However, aquaculture growth is likely to be moderate and the ocean catch will probably remain steady at current levels or even decline, leaving a marked gap between supply and demand, and also raising sh prices.

The process of development of a fishery as described by changes in landings with time is schematically represented in Figure 2 as comprising four phases: (I) undeveloped, (II) developing, (III) mature, and (IV) senescent. The phases are related to the relative rate of increase in yield of fish as the fishery grows. The relative rate of increase varies significantly as the maximum long-term yield is approached, reached and overshot. This idea can be used to

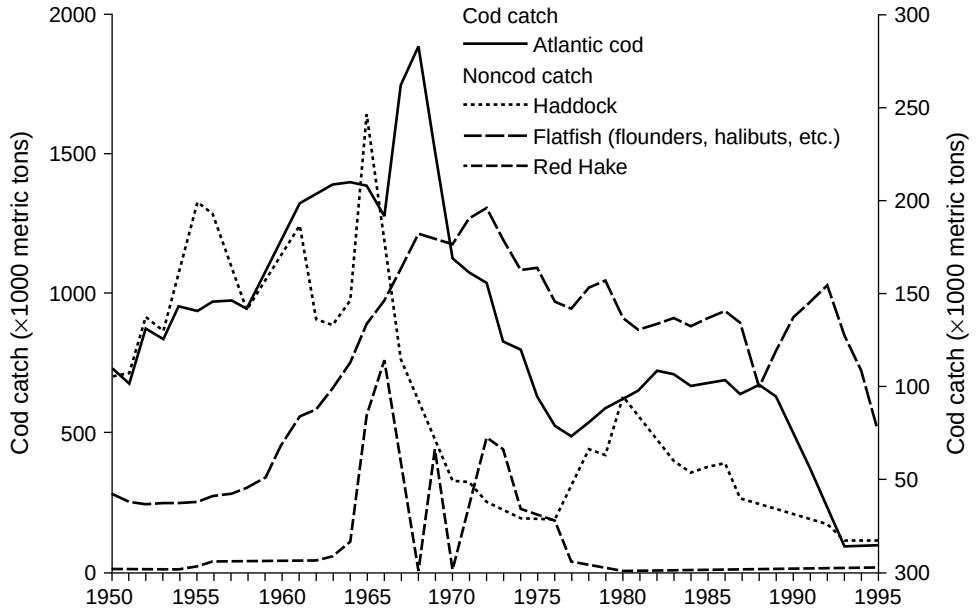

Figure 1 Commercial harvests in the Northwest Atlantic of some important fish stocks, 1950–1995 (*Source:* FAO, 1997c)

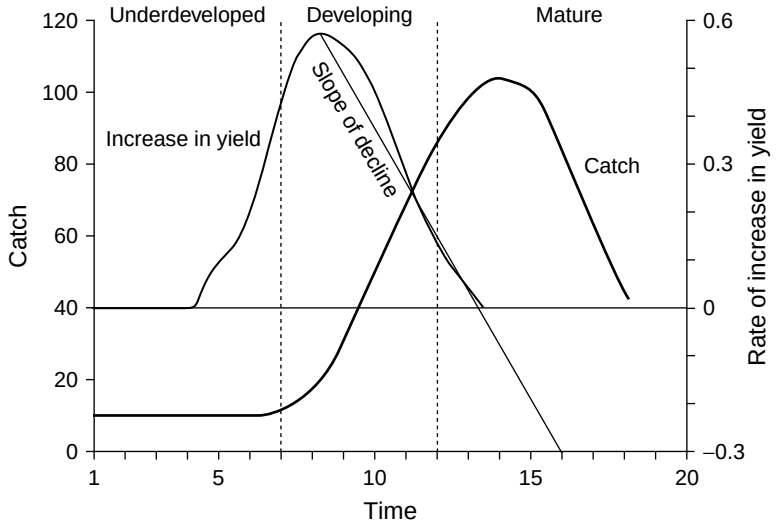

Figure 2 Theoretical development and decline of fisheries showing the derivation of the slope of decline used to predict future trends in world fish stocks (*After:* FAO, 1997c)

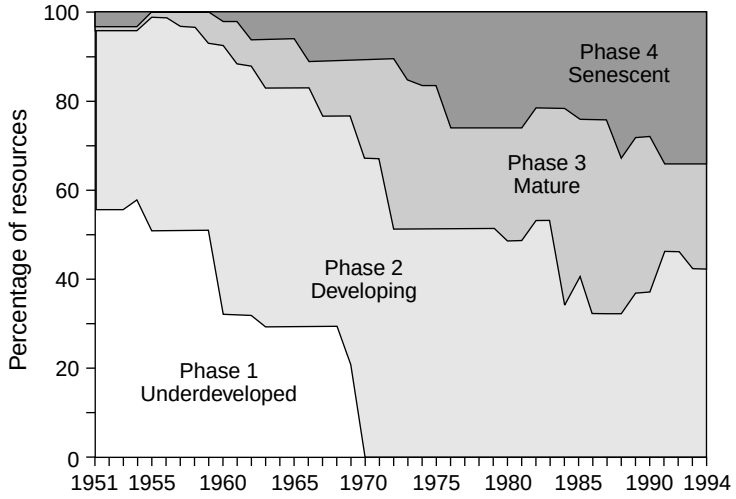

Figure 3 Percentage of the world's fisheries in differing stages of development 1951–1994 (*Source:* FAO, 1997c)

provide a rough assessment of the state of marine resources, globally and by ocean. The relative rate increase is nil in a stable non-developing shery (phase I), but increases rapidly (phases I II) as the shery starts to develop. During the phase of steady growth of the shery, it decreases (phase II) and drops to zero again when the shery reaches its maximum production (phase III). This theoretical pattern is masked by natural uctuations as well as by variability in the accuracy of sheries data. However, the way in which the relative rate of increase declines during phases II and III has been used by the FAO to estimate when full potential has been reached and what the corresponding potential multi-species yield could be.

By 1994 available data indicate that about 35% of the 200 major shery resources had become senescent (i.e., were showing declining yields), about 25% were mature (i.e., were leveling off at a high exploitation level), 40% were still developing, and none remained at a low exploitation (undeveloped) level (Figure 3). Earlier the FAO had concluded that 44% of the stocks for which formal assessments were available, were intensively to fully exploited, 16% were over- shed, 6% depleted, and 3% slowly recovering. These investigations indicated that 69% of the known stocks urgently needed strict management. A global production model used in this investigation indicated that the deepwater high value species were over- shed and that the global shing effort would have to be cut to rebuild the resources.

The decline in shery yields spread from the Atlantic to the Paci c and Indian Oceans as international shing eets went farther and farther from their home ports in the

Table 1 Progression of over-fishing from ocean to ocean, peak harvest year of high value (deepwater) fish by region

Fishing area	Year of maximum harvest	Maximum harvest (000 metric tons)	Recent harvest (000 metric tons)
Atlantic, northwest	1967	2588	1007
Antarctic	1971	189	28
Atlantic, southeast	1972	962	312
Atlantic, western central	1974	181	162
Atlantic, eastern central	1974	481	320
Pacific, eastern central	1975	93	76
Atlantic, northeast	1976	5745	4575
Pacific, northwest	1987	6940	5661
Pacific, northeast	1988	2556	2337
Atlantic, southwest	1989	1000	967
Pacific, southwest	1990	498	498
Pacific, southeast	1990	508	459
Mediterranean	1991	284	284
Indian Ocean, western	1991	822	822
Indian Ocean, eastern	1991	379	379
Pacific, western central	1991	833	833

search for good harvests (Table 1). In the western Atlantic, the breeding population of bluefin tuna, the largest tuna species, fell from around 250 000 adults in 1975 to around 40 000 in 1995. According to the US National Fish and Wildlife Foundation, 14 major commercial fish species in US national waters (accounting for one-fifth of the world s stocks and half of all US stocks) are so depleted that even if all fishing stopped immediately, it would take up to 20 years for stocks to recover.

Since 1994, efforts have continued to obtain international agreements to regulate exploitation of the global fisheries, especially in the case of fish stocks that straddle jurisdictions by migrating out of territorial waters into the high seas. Straddling fish stocks and highly migratory fish stocks have been vulnerable to depletion on the high seas in many regions of the globe:

1. pollock in the Donut Hole of the Bering Sea and the Peanut Hole of the Sea of Okhotsk;
2. orange roughy on the Challenger Plateau in the high seas off the coast of New Zealand;
3. hake, southern blue whiting and squid off Argentina s Patagonian Shelf;
4. jack mackerel off the coast of Chile and Peru; cod in the Barents Sea Loop Hole off the coast of Norway;
5. highly migratory stocks of tuna, dolphin, and shark in the South Pacific Ocean, beyond the limits of national jurisdiction.

A new international agreement was reached in 2000 to conserve the valuable tuna populations of the Western Pacific Ocean from which approximately half the supply of the world s tuna comes. However, the agreement by European ministers in 2000 to reduce fishing quotas for several commercial species in European waters will affect neither the long-distance fishing fleets from EU countries nor the fishing subsidies that fuel over-fishing. According to the World Wide Fund for Nature (WWF), the EU is subsidising its fishing industry by at least 14 000 Euro per fishing boat per year.

Despite the efforts to use aquaculture as a substitute for the harvest of wild fish (*see* Aquaculture and Environment: Global View from the Tropics to High Latitudes, Volume 3; Aquaculture in Asia, Volume 3; Aquaculture: Salmon Farming, Volume 3), farmed fish sometimes compete with native species and spread exotic diseases. Farmed Atlantic salmon often escape from net pens and invade wild populations. Perhaps as many as 40% of all salmon caught in the North Atlantic originate in farms. In addition, more than 255 000 Atlantic salmon also have escaped into the Pacific Ocean since the early 1980s and are routinely caught by fishing vessels from Washington to Alaska. It is possible that farm escapees may hybridize with and alter the genetic makeup of wild populations of Atlantic salmon. Such genetic alterations could exacerbate the decline in many locally endangered populations of wild Atlantic salmon.

CONCLUSION

World fish stocks are in serious decline. The collapse of the Grand Banks cod fishery and the virtual collapse of the cod fishery in the North Sea indicate the magnitude of the problem. Eleven of the world s 15 major oceanic fishing areas have been fished at or beyond their maximum sustainable yield for commercially valuable species and are in a state of decline. Sixty-nine percent of the world s commercial fish stocks are falling and urgent international action to restore them is required.

The fear is that because the cost of rehabilitation of natural fish stocks is escalating exponentially, the damage may become irreversible in some cases. Fish is the major source of protein for many of the world s poorest people, who will be the hardest hit by rising prices and scarcity of sh. The result may be even more exploitation and degradation of the land surface and its soils, as people attempt to substitute vegetables for sh in their diet. Degradation of marine sh stocks could thus eventually lead to further degradation of terrestrial ecosystems and soils.

Chernobyl

Burton Bennett
New York, NY, USA

The accident at the Chernobyl nuclear power station located in Ukraine near the border of Belarus occurred on the 26th April 1986. At the station were four reactors, each of 1000 MW capacity, of the graphite-moderated, light-water-cooled Soviet design known as RBMK-1000. Two of the reactors were constructed between 1970 and 1977 (Units 1 and 2) and two were completed in 1983 (Units 3 and 4). The accident happened during a test of the electrical control system as the Unit 4 reactor was being shut down for routine maintenance. The operators, in violation of safety regulations, had switched off important control systems and allowed the reactor to reach unstable, low power conditions. A sudden power surge caused a steam explosion that ruptured the reactor vessel and allowed further violent fuel steam interactions that destroyed the reactor and the reactor building. An intense graphite fire burned for 10 days before it could be brought under control, during which large amounts of radioactive materials were released to the environment.

The Chernobyl accident was the most serious ever to have occurred in the nuclear power industry. The accident caused the early death of 30 power plant employees and re ghters and resulted in widespread radioactive contamination in areas of Belarus, the Russian Federation, and Ukraine inhabited by several million people. In addition, enhanced radiation levels occurred throughout Europe, and trace levels were measurable everywhere in the northern hemisphere.

The radionuclides released from the reactor that caused exposure of individuals were mainly iodine-131, cesium-134 and cesium-137. Iodine-131 has a short radioactive half-life (8 days), but it can be transferred relatively rapidly through milk and leafy vegetables to humans. Iodine becomes localized in the thyroid gland. For reasons of intake of these foods, size of thyroid gland and metabolism, the thyroid doses are usually greater to infants and children than to adults. The isotopes of cesium have relatively long half-lives (cesium-134, 2 years; cesium-137, 30 years). These radionuclides cause long-term exposures through the ingestion pathway and from external exposure to these radionuclides deposited on the ground.

In addition to radiation exposure, the accident caused long-term changes in the lives of people living closest to the reactor, since measures intended to limit radiation doses included resettlements, changes in food supplies, and restrictions in activities of individuals and families. These changes were accompanied by major economic, social and political changes in the affected countries, resulting from the disintegration of the former Soviet Union.

Due to the seriousness of the accident, considerable measurements and assessments have been carried out by national and international organizations. The United Nations Scienti c Committee on the Effects of Atomic Radiation (UNSCEAR) conducted an evaluation of the average doses in separate regions of countries and for the population of the northern hemisphere as a whole that was published in the UNSCEAR report (United Nations, 1988) (*see* **UNSCEAR (United Nations Scienti c Committee on the Effects of Atomic Radiation)**, Volume 4). The experience gained in treating the immediate radiation injuries of workers and re ghters involved in controlling the accident was also reviewed in the UNSCEAR report.

The many measurements made following the Chernobyl accident have been useful to study the characteristics particularly of cesium behavior in the environment, the seasonal features of radionuclide transfers to foods and the enhanced accumulations that were observed in, for example, mushrooms, berries, lake sh, lichens, reindeer, and game animals. The methodology for estimating doses from such accidents have been improved. Due to the uneven deposition of radionuclides caused mainly by rainfall and the importance of particular foods leading to intake of radionuclides into the body, and because inadequate measurements

could be made at the time, especially of the short-lived iodine-131, the estimation of radiation doses to particular individuals requires time-consuming reconstruction efforts.

The average radiation doses to larger population groups in the most contaminated areas of Europe were of the order of 1 mSv or less in the first year following the accident. About twice the first year dose was received during the following few years. This may be compared with the average dose rate from natural background radiation of 2.2 mSv year^{-1}. In more contaminated areas surrounding the reactor, the average radiation doses were on average about 10 mSv during 10 years following the accident. The doses to the thyroid gland, were in some cases, much higher.

Large groups of people were evacuated from contaminated areas within days, weeks, or months after the accident, so the specific radiation doses depend on the particular circumstances of location, diet, age, etc., of each individual.

During the last several years, considerable attention has been devoted to investigating possible associations between health effects in the populations and the exposure to radionuclides released and dispersed following the accident. A review of these results is included in the UNSCEAR report (United Nations, 2000). Of particular note has been the occurrence of numerous thyroid cancers in children who lived in the severely contaminated areas of Belarus, the Russian Federation, and Ukraine. The number of cases, nearly 1500 between 1990 and 1997, is considerably greater than expected based on previous knowledge. The high incidence and the short induction period have not been experienced in other populations, and other factors are most certainly influencing the risk. If the current trend continues, further thyroid cancers can be expected to occur, especially in those exposed at young ages. The most recent findings indicate that the thyroid cancer risk for those older than 10 years of age at the time of the accident is leveling off, while the increase continues for those younger than 4 5 years in 1986.

Apart from the significant increase in thyroid cancer after childhood exposure, there is no evidence of a major public health impact 14 years after the Chernobyl accident. No increases in overall cancer incidence or mortality have been observed that could be attributed to ionizing radiation. The risk of leukemia, one of the major concerns after radiation exposure, does not appear to be elevated even among the workers who participated in the recovery operations after the accident. Neither is there any scientific proof of other non-malignant disorders, somatic or mental, that are related to ionizing radiation.

A majority of the epidemiological studies completed to date are of the geographical type, in which average population exposures are correlated with the average rates of cancer incidence in specific areas and time periods. As long as individual doses with reasonably low uncertainties are not available, the extent to which health effects might be radiation-related remains unclear. The reconstruction of individual doses is a key element in future research on radiation-associated cancers related to the Chernobyl accident. Although the Chernobyl accident could shed some light on our knowledge of the late effects of protracted radiation exposures, it must be recognized that because of the relatively low doses received by the majority of exposed individuals, any increase in cancer incidence or mortality will be difficult to detect in epidemiological studies.

Although the Chernobyl accident caused widespread contamination of local and regional areas of Europe and alarming short-term increases in radiation exposures of the population, the radiation exposures were, in fact, relatively small compared with those caused each year by natural background sources. The accident caused the disruption of the lives of many thousands of people in the immediate areas surrounding the reactor, and many health problems are being attributed to the accident. It appears, however, that the main radiological consequence is the occurrence of numerous thyroid cancers in exposed children. Continued studies will be needed to assess further the exposures and long-term effects of this most serious nuclear reactor accident.

Climatic Extremes

Kelly Sponberg
NOAA, Silver Spring, MD, USA

Increasing concern for global warming and wider, more rapid, media coverage of natural disasters have given climatic extremes greater prominence in human affairs since 1990. Perhaps fueled by the widespread impacts of events such as El Niño, or perhaps because of the activities of global organizations concerned with the environment and natural disasters, more and more people have become intrigued by the way climate creates both severe hardship and great bene ts.

Modern communications and environmental monitoring technology, especially weather satellites, have made us much more aware of extreme climatic events and associated disasters. Analyses of interlinked extremes, especially those associated with El Niño and La Niña occurrences have heightened our awareness of the impact of climate upon society and the important roles that climatologists with good regional knowledge can play in analyzing climatic variability/trends and using those analyses to reduce exposure to disasters.

The following discussion aims to provide a broad context within which to understand climatic extremes and the effect of these events upon society. Every extreme weather or climate event can teach us more about the interactions between humans and the environment. Rather than providing an exhaustive list of extremes, the following paragraphs present an overview of some key concepts and issues.

WHAT ARE CLIMATE EXTREMES?

Climate is simply the average of weather over a period of time. The climatic time scale may cover periods from months to centuries or millennia. Likewise, climate can be local, regional or global. It simply depends on what is being averaged, or more specifically the area and period of interest. In contrast, weather is always very local and measured in days if not hours.

Many weather extremes are a result of, and are fostered by, shifts in the background climate. Nevertheless, damaging weather events do not always reflect abnormal climatic conditions. Some climates always have events such as hurricanes and tornadoes embedded in them.

Most people are familiar with the threat that global warming poses and the warm Northern Hemisphere summers of the 1990s. However, the climate varies from year to year, from decade to decade and on even longer time scales. For instance, El Nino, a phenomenon characterized by warming sea surface temperatures in the Eastern Equatorial Pacific, can disrupt and alter global weather patterns. El Nino itself is a climate scale event, occurring every 2 7 years and requiring months to develop. The disruption caused by El Nino often persists for longer than a year: this global weather pattern has a profound effect on humans and the surrounding biosphere. Estimates of damages associated with the 1997 1998 El Nino place global structural losses at up to $60 billion and deaths reported at 21 000 (*see* El Nino and La Nina: Causes and Global Consequences, Volume 1).

Meteorologists and climatologists discuss extremes technically in terms of such physical phenomena as duration of drought, intensity and volume of rainfall and force of the wind, but most interest in climatic extremes results from the way in which society is affected by these events. For this reason, the popular media and general public think of climatic extremes as events resulting in significant human and property loss. In the past, meteorological records have often been inadequate to build up a picture of the physical characteristics and impact of climatic extremes. However, modern monitoring and information communications technology have permitted more consistent recording and description of these events.

Reconstructing the historical record of the interactions between humans and climate has been a painstaking but worthwhile task. For example, during the well documented winter El Nino events since 1950 (rainfall seasons of 1951 1952, 1957 1958, 1965 1966, 1968 1969, 1972 1973, 1977 1978, 1982 1983 and 1991 1992), rainfall averaged about 37% greater than normal, with a mean anomaly of about 190 mm at San Francisco (Montiverdi and Null, 1998).

THE IMPORTANCE OF CLIMATE EXTREMES

Not only does climate in some way determine the food humans eat, but it influences our fiber and building materials, how we construct our shelters, the clothing we wear, and our energy needs. It is not surprising then that shifts in our climate can greatly disrupt how society functions.

In many industrialized countries, climate extremes cause hardship and misfortune, but government support, emergency response and rescue services, as well as insurance mechanisms, allow for relatively quick recovery while minimizing major effects upon the local and national economy. Not all nations and people are so fortunate. However, events such as Hurricane Mitch, can wipe away decades of development in just a few days, if not moments. For many people it is only through international support and humanitarian aid that previously realized standards of living can be met once again. Even with such support, however, the development of many areas chronically suffers from repeated or sequenced climate extremes. For

example a series of droughts, floods, and storms brought severe hardship upon North Korea in the later half of the 1990s.

While most people will never witness firsthand, or be directly affected by, a climate- or weather-related disaster, increased globalization and international economic interdependence now mean that an event occurring continents away will in some way, even if very minutely, play a role in all our lives.

TRENDS VERSES TRUISMS

While we probably still do not know enough about changes in physical and human systems (and much less the interaction of these two) to be able to confidently say whether climate extremes, and their impacts, are either worsening or decreasing in severity, many current databases report an increase in the damage caused by climatic extremes. When looking at such databases, however, it must be remembered that our ability to observe and record such events has dramatically improved over the past century. We may not know the full impacts of earlier changes in climate and climatic extremes because of a lack of historical data.

The available careful analyses of trends within natural disasters and climate extremes all show that the costs associated with climatic extremes have increased, almost exponentially, over the past few decades. These studies, both global and regional, reflect both population growth and increasing investment in infrastructure and property. On the other hand, fatalities caused by extreme events appear to have decreased considerably. Even with the recent extremes such as hurricane Mitch (*see* Natural Hazards, Volume 3), flooding in Bangladesh, or the Venezuelan mudslides, fatalities due to climate extremes have been reduced considerably. Prior to World War II, several events caused deaths of 500 000 or more people; some events in Asia even resulted in several million fatalities. Again, modern technology and communications, including satellite telephony and helicopter rescues, assist in providing warnings and making evacuations from threatened areas.

Given these trends, on a global scale it remains difficult to determine if the number of climate extremes has increased or if the increasing losses are a result of demographic and societal changes. Studies of events in the US demonstrate that the frequency of most climatic extremes (droughts, floods, hurricanes, and tornadoes) has indeed remained relatively constant. There are some noted decadal fluctuations, such as with hurricanes, but again these do not yet point to a long-term change in event frequency. International experience is likely to be similar to that of the US. However this should not be permitted to obscure the possibility of long-term trends in the present-day climate extremes. Indeed, one lesson is that if natural climatic variability can and does cause significant damage, we should not be surprised that changes in our climate will affect us in more severe ways.

Despite the use in recent years of the term *climate surprise*, to describe events resulting in severe damage, which were not entirely predicted, it should be readily clear that on a longer time scale, surprises do not exist. Fast or slow, harsh or soft, climate variability is a constant, which will continue to significantly affect us.

EXAMPLES OF CLIMATIC EXTREMES

Drought

Drought occurs when an area receives less than normal rainfall over an extended period of time. The exact definition varies among different climatic zones, nonetheless drought can affect any part of the globe.

The human perception of drought is dependent upon the traditional use, and access to, water. People only become aware of drought when human consumption of water and activities using water are hindered by a reduction in precipitation. Not surprisingly, marginal populations dependent upon water for agriculture and transportation are particularly vulnerable to climatic fluctuations that bring about drought in their region.

The most striking feature of drought is that it develops slowly and usually takes a long time to dissipate. As such, the effect on property and populations is a creeping phenomenon that is often hard to notice in its early stages. It is not unusual for a drought to last several years, and as a result the damage to agriculture and food supplies has often led to famine and displaced populations. In severe cases disease often spreads as food supplies dwindle and water supplies become contaminated. Even after a drought subsides, there are often losses that continue to accumulate as a result of land degradation or human migration.

In the early 20th century, China suffered severe droughts and related famines. From 1907 into the early 1940s, more than 35 million died from starvation. The worst impact occurred in the drought of 1907 when upwards of 24 million people died.

Of course other parts of Asia have also suffered from drought. In India the drought of 1900 claimed up to 3.25 million lives. In the Bengal drought of 1943, 1.5 million lives were reportedly lost, and another 1.5 million perished in the 1965 1967 drought famine.

Even in more recent years, drought has continued to affect the Asian landscape. During the 1997 1998 El Nino, dry conditions over much of Indonesia resulted in some

$3 billion worth of damage to crops and property. In addition many associated fires destroyed a reported 3.3 million hectares of land.

Many severe droughts affected Africa throughout the 1970s, particularly in the Sahel of Western Africa. Drought and famine between 1972 1975 claimed over half a million lives. A similar drought occurred between 1984 and 1985, but during this episode some 20 African nations were affected. Among these was Ethiopia, which suffered from prolonged drought from 1981 1985. Some estimate that during the worst period of the event, as many as 20 000 children died a month in Ethiopia.

Drought, however, does not always result is famine or a loss of life. The impacts are dependent upon government, economic, and social support structures. Again, marginalized people are ultimately at a greater risk from drought and other climate extremes.

A severe drought in the US from 1932 1940, also known as the American Dust Bowl, did not result in loss of life or famine but caused severe and long lasting loss of topsoil and associated land degradation. Nonetheless, it severely affected human lives. Some 350 000 farmers were displaced. The drought that affected the US between 1987 and 1989 produced total losses across many sectors of the economy of $39 billion, making that event the most costly recorded climate extreme in US history.

Floods

Floods vary greatly in extent and duration, depending on the size of the river basin in which they occur and the space, time, duration characteristics of the precipitation event, and/or snow melt, producing them. The damage they cause may be exacerbated by the severity of the event, occupation of the flood plain, population density, relative wealth of affected communities, as well as human structures such dams and levee banks. Although flash floods cause a significant amount of damage, the most severe events are often associated with widespread regional flooding in large river basins.

Some of the most extreme flood events have occurred along the Yangtze River in China, where some flooding is expected every year sometime between June and September. However, climatic fluctuations, compounded by changes in land use, can and have caused floods that exceed the capacities of levees and other water control measures. The worst flooding along the Yangtze occurred prior to the end of World War II in which three floods in 1928, 1931, and 1939 each caused over half a million deaths. The event of 1931 was particularly destructive as it resulted in 3.7 million fatalities while affecting another 28 million people. Damage from the event has been estimated at $1.4 billion. The flood of 1931 came at particularly bad time in that it followed the 1928 1930 drought, which itself followed/coincided with the 1928 flood along the Yangtze.

Flooding along the Yangtze continues to cause severe damage today, however the loss of life is much less. Instead, losses are mainly in terms of infrastructure. In 1991 flooding in China caused an estimated $9 billion dollars worth of damage. In 1996 the costs were reported at $20 billion, and as a result of the severe flooding in 1998, $30 billion dollars worth of damage occurred.

Flooding can occur anywhere that rain falls. In central Europe, floods occur along the Danube and its tributaries frequently as a result of snowmelt or heavy rain. In 1838 flooding associated with melting ice in the Danube Valley reportedly destroyed half of Budapest. Although other floods caused significant damage throughout the 20th century, the floods of 1997 were particular destructive. Two weeks of heavy rainfall in July of 1997 caused flooding along the banks of the Danube in Hungary, Austria, and Slovakia. Flooding north of the Danube basin, along the Oder River extended the damage into Germany and Poland. 0.61 million hectares in Poland were flooded with 1360 towns and villages being inundated. In Poland alone, estimated economic losses were placed at $3 billion.

Another historic flood occurred along the Mississippi River in 1993 after record rainfall occurred in the months of June and July. In some places, rainfall was reportedly as much as three or four times above normal. As the rivers connecting to the Mississippi swelled throughout the summer, flooding began to occur downstream of St. Louis as levees broke. In all, some 8.1 million hectares of farmland were flooded and 46 fatalities occurred. Direct economic losses were estimated at $12 15 billion; however, the long term costs to productivity and losses associated with displacement of families were far greater (*see* **Natural Hazards**, Volume 3).

Tropical Cyclones

Tropical cyclones, known as typhoons, cyclones, or hurricanes depending upon the region of the globe, are massive storms created over the oceans. The areas most severely affected by these events are coastal regions, slightly inland areas, and islands located at latitudes greater than five degrees. Although each tropical cyclone is really an individual weather event, these storms are worth mentioning in the context of climate extremes, not only for the severe damage they cause, but also because variations in climate can increase the frequency and intensity of these events. The every-few-years occurrences of the El Niño Southern Oscillation, a phenomenon in the Equatorial Pacific Ocean, is known to affect the Atlantic Ocean hurricane season.

Posing a triple threat of strong winds, storm surges, and heavy rainfall, tropical cyclones can cause very localized and severe damage. On August 24, 1992, category four, Hurricane Andrew caused severe damage along a 100 kilometer path across Southern Florida, US. Winds and floods destroyed 25 524 homes while damaging another 101 241. After striking Florida, Hurricane Andrew made landfall once more in Louisiana as a category 3 hurricane. Sixty-one lives were lost in this one hurricane, and the total cost of the damage in the US was estimated at $26 billion. Well before Andrew, however, hurricanes had caused severe damage in the Atlantic and Gulf of Mexico. On September 8, 1900, Galveston, Texas was stuck by high winds and storm surges from a hurricane. Over half the city was demolished and 10 000 people were left homeless. Prior to the storm Galveston was an up and coming port city, which took advantage of its location and natural harbor. Unfortunately, the city was only some two meters above sea level, thereby leaving it particularly vulnerable to storm surges and flooding. Following the Galveston hurricane, the city built a sea wall to protect itself from future storm surges.

Of all the other low lying areas affected by repetitive flooding associated with tropical cyclones, Bangladesh faces the most severe problems. Most of this densely populated nation is just above sea level, occupying the joint delta of the Brahmaputra and Ganges Rivers. In 1970 a cyclone affected Bangladesh resulted in the worst tropical cyclone damages recorded in the 20th century. As many as 500 000 people were believed to have perished as a result of storm surges and high winds. Construction of storm shelters and other mitigation strategies have greatly reduced the loss of life due to cyclones, however these storms continue to menace the area. In 1991 cyclone 02B struck Bangladesh causing 150 000 deaths and some $1.5 billion worth of structural damage.

Conjunctive Events

Conjunctive climate extremes are events where the impacts are compounded by a concurrent event or when the initial climatological event triggers a man-made disaster. In truth any climate extreme that impacts humans is in someway a conjunctive event, as it likely disrupts agricultural production, transportation, utilities, etc. The famine caused by drought is often the failure of agricultural and food supply systems. Epidemics that result from climatological events are often caused when sanitation and nutrition suffers.

However, a clearly conjunctive event occurred in Egypt in November of 1994 when heavy rains triggered flooding in the southern provinces of the country. On November 2nd, flooding in the province of Asyut toppled a fuel transport which then ignited. Burning fuel on top of floodwaters destroyed several villages. What was not destroyed by water was burned. In total over $140 million worth of damage occurred, 11 000 houses were destroyed, 11 000 houses were damaged, and 110 000 people were affected.

CONCLUSION

The severe impacts of climatic extremes described above emphasize the direct impacts on human beings and economies. The indirect impacts on human society through the effects of climatic extremes on ecosystems may be even greater. The feedbacks from droughts, which dry up stream beds and lower groundwater tables, are felt rapidly by urban societies if water rationing is introduced. Their impacts on rangeland ecosystems grazing stock and irrigated soils may be slower to reach crisis proportions, but can undermine rural economies and eventually affect urban food supplies. Such processes can produce environmental refugees (*see* Environmental Refugees, Volume 4) and even be a factor in civil conflict and war, which in turn can lead to environmental damage (*see* Environmental Changes Driven by Civil Conflict and War, Volume 3). Climatic extremes can readily induce premature deaths, as when elderly people die during heat waves, or people with bronchial ailments die during urban smogs (*see* Urban Sulfurous and Photochemical Smog, Volume 3).

However, people are not the only organisms affected by climatic extremes. Damage, particularly to small island habitats, can greatly reduce or eliminate the habitats of key animal and bird species. Droughts may desiccate small ponds and wetlands, killing species which are unable to adapt to drought conditions. On the other hand, widespread floods in inland Australia usually result in the germination of many dormant seeds, creating a beautiful carpet of wildflowers extending for dozens of kilometers. There are clear thresholds of environmental stress which individual species populations and plant and animal communities can withstand. Yet there is uncertainty over the frequency and duration of the extremes which produce those thresholds. Many suspect that ecosystems have a certain resilience to climatic extremes, which means that their response lags behind climatic change, but detailed palaeoclimatic investigations are only beginning to demonstrate whether or not that is the case.

Common Agricultural Policy (CAP)

Ian Bowler
University of Leicester, Leicester, UK

The common agricultural policy (CAP) of the European Union (EU) comprises the world's most advanced form of supra-national law and institutional regulation. Despite several attempts at reform, most of the objectives and measures initially negotiated by the member states in the 1950s remain, albeit modi ed to some extent. The pace of reform has been increasing, however, with the reduction in the CAP's protectionist measures under trade liberalization by the World Trade Organization (WTO) and the integration of the CAP into a broader rural development policy for the EU.

The CAP has had a range of positive and negative consequences, the latter now outweighing the former. The main positive bene ts include obtaining security of food supply for consumers in the EU, raising average farm incomes and funding a modernizing and increasingly ef cient farm sector. The principal negative consequences of the CAP have been the production of agricultural surpluses, the disruption of international trade, the restructuring of rural economies and societies, the high nancial cost to EU consumers and taxpayers, and degradation of the environment, especially as regards resources of water, soil and natural habitat.

INTRODUCTION

The CAP of the EU comprises the world s most advanced form of supra-national law and institutional regulation. The objectives and basic principles of the CAP were negotiated by the original six member states of the (now) EU between 1957 (Treaty of Rome) and 1962, with the first measures for a common market in cereals being introduced after 1967 (Bowler, 1985). There have been a number of subsequent reform periods, for example following the Mansholt Plan of 1968 and the MacSharry Reforms of 1992. However, the objectives and measures of the original CAP tend to have been modified and added to, rather than displaced.

OBJECTIVES

The objectives of the CAP are contained in Articles 38, 39 and 110 of the Treaty of Rome, namely: to incorporate agriculture within the common market; to increase agricultural productivity by promoting technical progress; ensuring the national development of agricultural production and the optimum utilization of all factors of production, particularly labor; to ensure a fair standard of living for the agricultural population, particularly by increasing the individual earnings of persons engaged in agriculture; to stabilize agricultural markets; to guarantee regular food supplies; to ensure reasonable prices in food supplies to consumers; and to support the harmonious development of world trade (Fennell, 1997). Many of these objectives are contradictory (e.g., forming a common market and creating harmony in world trade), others are open to political interpretation (e.g., a fair standard of living), while an environmental objective was not introduced until the early 1970s (Brouwer and Lowe, 1999).

PRINCIPAL MEASURES

Seven principal measures have underpinned the CAP: (1) internal commodity price guarantees, but at levels above world market prices, through target prices and intervention agency buying for each of the main farm products; (2) variable import levy protection of the internal market against imports, based on threshold prices; (3) export subsidies for the main farm products in surplus; (4) direct

income supplements for farms in defined areas (e.g., the less favored areas, 1975); (5) financial incentives for farm modernization, farmer retirement and farmer training; (6) limits on production (co-responsibility levies, budgetary stabilizers, production quotas, set-aside of arable land, 1988); and (7) a centrally financed farm budget (i.e., the European Agricultural Guidance and Guarantee Fund (EAGGF)).

The allocation of funds under the EAGGF has favored the guarantee (over 60% of expenditure of the CAP until the late 1990s) over the guidance section. Within the guarantee section, a few farm products have received the majority of price support, either through intervention buying and storage or export subsidies (e.g., milk, cereals, beef until the early 1990s and subsequently crops). The guidance section provides direct income payments and financial assistance for the modernization of farms, food processing and marketing, including the early retirement of farmers.

REFORMS OF THE CAP

Attempts have been made annually, since the early 1980s, to reduce the real value of farm price supports, the degree of protection afforded to internal markets and the level of export subsidies. Progress has been slow, however, and has tended to be overtaken by the rate of increase in agricultural productivity, as reflected in the volume of farm production. Eventually farm output has had to be limited by various types of production quotas, beginning in 1984 with milk, although limitations on sugar beet had been in operation much earlier. The pace and scale of reduction in price supports have been intensified during the 1990s, initially under trade liberalization by the General Agreement on Tariffs and Trade and latterly by the WTO.

Table 1 Selected MacSharry Reforms agreed by the Council of Ministers, 1992

Twenty-nine percent reduction in cereal support prices over three years
Compensation for rotational set-aside (a percentage of a base area)
Cross-compliance between set-aside and area-based income payments on arable production
Removal of co-responsibility levies
New non-rotational set-aside
Accompanying measures providing aid for environmental protection, forestry and early farmer retirement
Quotas in the beef, sheep and milk sectors

Source: adapted from Kay (1998).

Following the 1992 MacSharry Reforms (Table 1), arable area-based direct payments have been added to the principal measures of the CAP as a new form of income supplement, linked in cross-compliance to farm-based set-aside (e.g., 10% of a farm s 1989/1991 base area). Livestock headage payments (beef cattle and sheep) have been limited to fixed stocking densities, as a form of quota. Agri-environmental measures have been introduced through national agri-environmental programs (AEP) as accompanying measures, including payments for the development of organic farming; and financial assistance has been made available for the afforestation of agricultural land. In broad terms, the attempt is being made to decouple farm incomes from the volume of agricultural production.

COSTS AND BENEFITS OF THE CAP

The CAP is associated with a range of positive and negative consequences, the latter now outweighing the former. The main positive benefits include obtaining security of food supply for consumers in the EU, raising average farm incomes and funding a modernized and increasingly efficient farm sector. These benefits are often overlooked in assessments of the CAP, but the improvement in nutritional standards amongst the population of the EU, the assurance of food supplies at reasonable prices to consumers, and the marked increase in quality of life for most of the farm population since the immediate post second world war years cannot be dismissed lightly.

The principal negative consequences of the CAP include the production of agricultural surpluses, the restructuring of rural economies and societies, the high financial cost to EU consumers and taxpayers (e.g., 45 600 m ECU in 1998), and degradation of the environment, especially as regards resources of water, soil and natural habitat. Production surplus to domestic demand initially attracted most political attention, for it was achieved at costs and prices in excess of those on the world market. Surpluses necessitated purchase and storage by intervention agencies (e.g., cereal mountains and wine lakes), and then destruction, export under subsidy, or disposal as food aid. The latter two strategies then served to destabilize national markets in developing countries and international markets for agricultural exporting countries, such as the US, New Zealand, Brazil and Argentina.

Nor have the benefits of the CAP been evenly distributed within the farm sector (Laurent and Bowler, 1997). Most benefit has been to the producers of a relatively few farm products, located in the northern member states, and occupying larger farms. Nor did the CAP protect the farm sector from the economic forces of restructuring, resulting in the migration of a majority of farm workers to the cities, followed in later years by the occupiers

of small and increasingly marginalized farms. In addition, modernized, intensi ed and increasingly large farms have implemented farming practices damaging to the environment, including the pollution of water resources from the excessive application of inorganic fertilizers and the disposal of animal manures on both crop and grass land, the loss of natural habitats, and threats to food health and safety through pesticide residues, infection of food and livestock diseases.

CONCLUSION

The CAP continues to evolve, with new regulations and nancial incentives being provided, to guarantee food quality and safety, deepen and extend the MacSharry Reforms under Agenda 2000 (e.g., further movement from price supports to direct income payments, extending milk quotas, and transferring more funds to the Guidance section of the EAGGF). This last dimension re ects the integration of the CAP into a broader rural development policy for the EU, including the redesignation of Objective 1 and 2 regions for receiving funding and through which agriculture becomes integrated into, rather than separated from, the development of regional economies.

Consumption Patterns: Economic and Demographic Change

Jyoti Parikh
Indira Gandhi Institute of Development Research, Mumbai, India

Consumption patterns vary with demographic, economic and cultural differences. Total consumption, of course, goes up as population and income increase, but the structure of that consumption and growth rates of different segments of that structure are revealed by demographic indicators such as rural and urban, age and gender composition of the population among other indicators. Secondly, there is a reverse linkage in that consumption levels in uence demographic variables such as fertility life expectancy and mortality. However, it is difficult to consider the impact of demographic changes separately, without discussing economic prosperity and income levels. Economic prosperity is one of the major forces that drives consumption. In their contribution to Earth Summit at Rio, Parikh et al. *(1991) showed for the first time that 25% of the global population with high income levels in developed countries consumes 75% of the world s resources. Subsequently, Agenda 21 drew attention to consumption and production patterns. Since then, consumption patterns have become a widely recognized issue addressed by researchers, consumer associations in various countries and international organizations as well as in seminars and in print-media. The human development report by the United Nations Development Programme (UNDP) (UNDP, 1998) also devoted a special issue to this topic.*

A breakdown of several commodities by world regions is given in Table 1. What is consumed at various income levels? At a low income, i.e., at subsistence level, one usually consumes primary goods such as cereals, milk, meat and fuelwood. With further rise in income, secondary goods such as petroleum products, cement and fertilizers enter the consumption basket. Finally, at a high income, tertiary goods such as transport vehicles, consumer

goods and appliances and material-intensive services are demanded. Not all consumption at a high income is material intensive perfumes, jewelry, and restaurant services, e.g., do not require much material. Thus, consumption levels depend on the kind of population that is growing rich or poor.

Vastly different consumption patterns can be seen in rural and urban areas, especially in developing countries. Some of the differences may be due to low availability of infrastructure and availability of merchandise in the rural areas. For example, in India 70% of the population still lives in rural areas. The ratio of *per capita* expenditure by the rural and urban populations may indicate the disparity. The ratio of the *per capita* expenditure of the average urban person to that of the average rural person is the *rural to urban disparity ratio* (RUDR). These ratios are presented in Table 2 for different commodity groups. On the average, top 10% in urban areas have *per capita* expenditure 9.2 times larger than the rural bottom 50%. While these are large differences within a country, the urban top 10% in India have much lower consumption levels than the average European or North American.

When rural people migrate to urban areas or developing country residents migrate to a developed country, the consumption increases and the patterns also change. Apart from income differences, the change is primarily due to differences in infrastructure such as roads, highways, public transport, airports, power plants, water supply, hospitals and many other services not available often in the rural areas. Despite their ability to pay, rich people in developing countries end up sharing poor infrastructure with the rest of the population. This explains why in developing countries, even very rich persons do not consume as much as an average person in developed countries (World Resources Institute, 1994). Infrastructure differences arise from different investment levels. Thus, investment patterns public and private also determine consumption patterns.

Another critical demographic variable is age structure, e.g., young people require schools, books, goods for sports and travels, whereas seniors require facilities such as hospitals, diagnostic centers and medical care centers. In developed countries, the relatively affluent senior citizens often contribute to a rise in leisure industries. In the developing countries, they depend on their children to take care of them. Their consumption usually falls with age.

Gender also affects consumption patterns i.e., females have different consumption patterns from males. Not many data are available but the differences are particularly evident in the poor households where women do not often get to voice their preferences. Moreover, on their own, a woman puts the interests of her home, children and male members of the family ahead of her own desires.

Cultural differences and investment patterns determine consumption patterns. With globalization, the cultural differences gradually vanish or get blurred.

Consumption *per capita* is highest in the wealthy countries that have both high average personal wealth and high investment in infrastructure and social support systems such as transportation, utilities, hospitals, educational facilities and so on. Such wealthy countries also often have the highest per capita expenditure on military hardware and weapons, adding to the proportion of global resources they consume. All this suggests that consumption by well-off people of wealthy countries is a disproportionately large driver of global environmental change.

Why should consumption levels matter? Sovereign nations do not like to discuss their consumption patterns. Similarly, within nations also people prefer to have freedom to choose their own levels of consumption. However, in addition to inequity in resource utilization, there are some environmental issues which link rich and poor within and across nations. Consumption patterns manifest themselves in environmental degradation such as contributions to ozone depletion and greenhouse gases (GHG) accumulation that pose a threat of global climate change (*see* National Responsibilities for Greenhouse Gas Emissions, Volume 3), pollution of the sea, accumulation of hazardous waste and nuclear wastes causing various types of global

Table 2 Disparity in per capita annual private consumption expenditures, 1989–1990, India[a,b]

[b] The commodity groups are formed by aggregating the sectors of input-output matrix for India brought out by the Planning Commission. Each element describes how much inputs of various other commodities are required to produce one unit (value in rupees, say thousand rupees) of that commodity.

environmental stresses apart from resource shortages that follow excessive use. If the consequences of consumption have to be suffered by everybody, it is not a sovereignty issue or freedom of choice. If zero pollution is assured or if environmental concerns are fully internalized for all economic activities, people and countries have the freedom of choice. When this is not so, debate arises.

What can be done by the people?:

- Analyze consumption trends and driving forces along with their economic, environmental and social impacts.
- Involve local communities in addressing this issue in their own context to collectively come up with plans and measures.
- Develop an ethos that rewards the wise use of resources and sets standards to which all societies can aspire. Here media and manner of advertising have a role to play.

Thus, income levels dictate consumption patterns to a large extent, but the demographic variables such as population, rural and urban population shares, age structure and gender also play an important role.

Critical Load

The term *critical load* was first used in the 1980s to define atmospheric deposition limits for sulfur (S) and nitrogen (N) pollutants for preventing acidification. An early definition (Nilsson, 1986) describes a critical load as the highest load that will not cause chemical changes leading to long-term harmful effects on the most sensitive ecological systems. By the late 1980s, the critical loads approach was being discussed as a means for setting pollution emission limits through modeling deposition patterns from emission sources and comparing them with critical loads. While various attempts were made to refine the definition for specific purposes (Bull, 1995), a general definition dating from 1988 (Nilsson and Grennfelt, 1988), was adopted in work under the United Nations Economic Commission for Europe (UN/ECE) Convention on Long-range Transboundary Air Pollution (CLRTAP) (UN/ECE, 1996) for a manual on mapping critical loads (UBA (Umweltbundesamt), 1998): a quantitative estimate of exposure to one or more pollutants below which significant harmful effects on specified sensitive elements of the environment do not occur, according to present knowledge. The manual summarizes agreed methods for calculating critical loads for acidity and eutrophication. It also describes ways of estimating critical levels, thresholds for the direct effects of pollutant gases. Critical loads or critical limits have also been used more recently for other pollutants, e.g., some heavy metals, where there are clearly defined thresholds. However, the term *critical load* is different from traditional ecotoxicological limits, being best applied to ecosystem effects for elements or compounds that are essential to life (Brydges, 1991). They are (usually of necessity) set close to damage levels whilst margins of safety are applied in ecotoxicology (Bull, 1994). In recent years, the European Union, in its Acidification Strategy, and the CLRTAP, in its protocols, have identified critical loads as their key environmental objectives to be achieved through pollution emission decreases (Bull and Fenech, 1999).

Curi, Kriton

(1942 1996)

Kriton Curi, Turkish scientist, pioneer, environmentalist, Professor of Civil Engineering at Bogazici University (Turkey), was the founder and director of the Turkish National Committee on Solid Wastes, and the Institute of Environmental Sciences.

He was the director of the Institute of Environmental Sciences, acting chairman of the Civil Engineering Department and a Senator at Bogazici University Senate at various times. Professor Curi was an active member of nine national and international professional associations, he was on the editorial board of three scienti c journals and he was the editor and author of 17 books and more than 100 articles.

Professor Curi had a very strong personality, valuing honor, friendship and loyalty. He was a highly motivated, principled, creative, open minded and self con dent scientist who had clear ideas; he would defend his beliefs and work towards his objectives courageously and with all his means, as if he were on a divine mission. He was the rst scientist in Turkey to create public awareness about environmental protection. He also introduced the concept of appropriate technologies for developing countries.

Professor Curi was principled, uncompromising and persistent regarding:

- national and international laws and by-laws regarding the environment;
- the elimination of environmental damage;
- laws and by-laws on higher education;
- improvement of the quality of university education.

His ideals always had a much higher priority than his personal gain. For example, even though he gave frequent talks and seminars, he would not accept an honorarium or fee; he would rather have the host institution give support to environmental protection, at least plant a tree in memory of the day.

Professor Curi was an industrious academician who loved his job and his students:

- even when he had demanding administrative duties, he would still teach 3 4 courses per semester;
- whenever he visited a town for the rst time, he would visit its solid waste removal site before its downtown;
- he frequently would go to high school students gatherings to speak about environmental problems at a level that students would understand.

Professor Curi was a tireless and effective organizer; he was constantly arranging national and international scienti c meetings, symposiums, seminars and fairs. But above all, Professor Curi was a devoted environmentalist and humanist, promoting harmony between humans and nature and peaceful coexistence between communities and nations. In the last decade, there has been almost no environmentally related national event or action and few international ones that Professor Curi has not been af liated with. These projects include:

- promoting cooperation between Turkey and Mediterranean Countries against forest fires;
- organizing an international conference of Mayors of Mediterranean cities to discuss common environmental issues;
- enhancing cooperation between Turkish and Greek industrialists to reduce water and air pollution in the Aegean Region;
- accomplishing the Vision of International Charter on the Environment by Students (VOICES) Conference, the first and the only environmental conference of students participating from all over the world.

That he was actively pursuing the projects at the time of his unfortunate and unexpected death, is clear evidence of his strong desire to enhance peace and cooperation in the volatile Middle-East Region.

Professor Dr Kriton Curi received many national and international awards and 90 plaquettes given by different institutions and non-governmental organizations for his contributions to the environment. A Kriton Curi Environmental Foundation has been founded in his memory.

Deforestation and Habitat Fragmentation in the Amazon Basin

Compton J Tucker, David Skole, Marc K Steininger, John R G Townshend, and Walter Chomentowski

NASA/Goddard Space Flight Center, Greenbelt, MD, USA

Tropical forest extent and deforestation in ~8 000 000 km^2 of the Amazon and Basin of South America were mapped using Landsat satellite images from the mid-1980s and early 1990s. Forest cover extent, including evergreen and deciduous forest, totaled 6 344 000 km^2, while the area of natural non-forest formations totaled 2 000 000 km^2. The area deforested totaled 58 000 km^2 in the middle 1980s; an additional 46 000 km^2 was deforested by the early 1990s. These data document a spatially concentrated deforestation zone in the Eastern and Southern Amazon Basin where deforestation is occurring at an accelerating rate. Contrary to popular perception, tropical dry forests are being cleared at faster rates than any other forest type in the Amazon Basin.

INTRODUCTION

Deforestation has occurred in the tropics throughout history (Tucker and Richards, 1983; Richards, 1984; Hecht and Cockburn, 1989; Williams, 1989, 1990) and has accelerated recently, particularly in areas of seasonally deciduous tropical forests (Schmink and Wood, 1984; Janzen, 1986; Fearnside, 1986, 1993; Houghton *et al.*, 1991; Myers, 1991; Skole and Tucker, 1993; Maas, 1995; Steininger *et al.*, 2000a). Accurate information on the extent of tropical forests and deforestation is essential for estimation of changes in surface energy balance and atmospheric greenhouse gas emissions (Cook *et al.*, 1990; Gash and Shuttleworth, 1991; Houghton, 1991; Keller *et al.*, 1991; Dixon *et al.*, 1994; Fearnside, 1996) and in terms of the global water balance (*see* Deforestation, Tropical: Global Impacts, Volume 3). Precise information about the spatial distribution of deforestation is also necessary to estimate the impacts of habitat destruction and fragmentation on biological diversity (Harris, 1984; Skole and Tucker, 1993; Pimm *et al.*, 1995; Laurence and Bierregaard, 1997; Laurence *et al.*, 1997, 1998; Chiarello, 1999).

Remote-sensing analyses of the Amazon, the largest area of tropical forest on the planet, have demonstrated dynamic deforestation frontiers, particularly in areas near highways or where industrial-scale agriculture is occurring (Fearnside, 1986; Skole and Tucker, 1993; Steininger *et al.*, 2000b). Deforestation in these areas causes high levels of fragmentation of the remaining, uncut forests. This is significant because forests near clearance edges are susceptible to an array of human and bio-climatological impacts (Malcolm, 1994; Laurence *et al.*, 1997, 1998; Cochrane and Schulze, 1999; Nepstad *et al.*, 1999) and the isolation of forest fragments affects local composition and biodiversity (Miller and Harris, 1977; Wilcox, 1980; Karieva, 1987; Laurence *et al.*, 1999; Gascon *et al.*, 2000). It is thus necessary to consider the isolation of forest fragments and the contact zone between deforested areas and intact tropical forest when quantifying the effects of deforestation upon biological diversity. The cumulative affected area of tropical forest where biological diversity is negatively impacted has been reported to be two to three times the actual deforested area (Skole and Tucker, 1993; Steininger *et al.*, 2000b).

Much of the controversy surrounding estimates of tropical deforestation arises from the lack of wall-to-wall measurements. Significant errors result from attempts to estimate tropical deforestation using a sampling approach, because tropical deforestation is highly concentrated spatially (Fearnside, 1986; Skole and Tucker, 1993). Any sampling attempt that does not take this into account will generate highly inaccurate estimates of deforestation (Tucker and Townshend, 2000; Sanchez *et al.*, 1997). Until recently, coarse resolution (• 1 km) satellite imagery has been the only source of data with wall-to-wall acquisitions, largely because fine-resolution imagery has been commercialized and thus expensive (Goward and Williams, 1997). Tropical forest extent has been mapped

with coarse-resolution satellite data (Tucker *et al.*, 1984; Malingreau and Tucker, 1988; Hansen *et al.*, 2000). However, most changes in forest cover occurs in small (• 10 km^2) patches which can not be reliably detected with these data.

AMAZONIAN DEFORESTATION

A systematic study of forest extent and change throughout large areas, such as the Amazon Basin, is only possible through the use of high-resolution satellite data. The data set we report are results from digital analysis of Landsat Multispectral Scanner (80-m resolution) and Thematic Mapper (30 m-resolution) satellite data, coupled with a geographic information system (GIS) to manage the analyzed data.

We classified each Landsat image into seven unique classes (forest; deforestation; regrowth; cerrado or savanna; water; cloud and shadow; and other) and merged these classes into a seamless spatial database. A total of 390 Landsat images have been analyzed for up to three time periods. Each Landsat scene was classified individually since atmospheric and viewing-geometry conditions varied among scenes. The only other alternative would be to attempt normalization of all the data to a constant sun target sensor geometry under specified atmospheric conditions and assume the land surface was invariant. This approach is impossible to achieve with Landsat data alone and was not attempted. However, it may be possible through combined analyses of new satellite data from the Landsat-7 and Terra satellites.

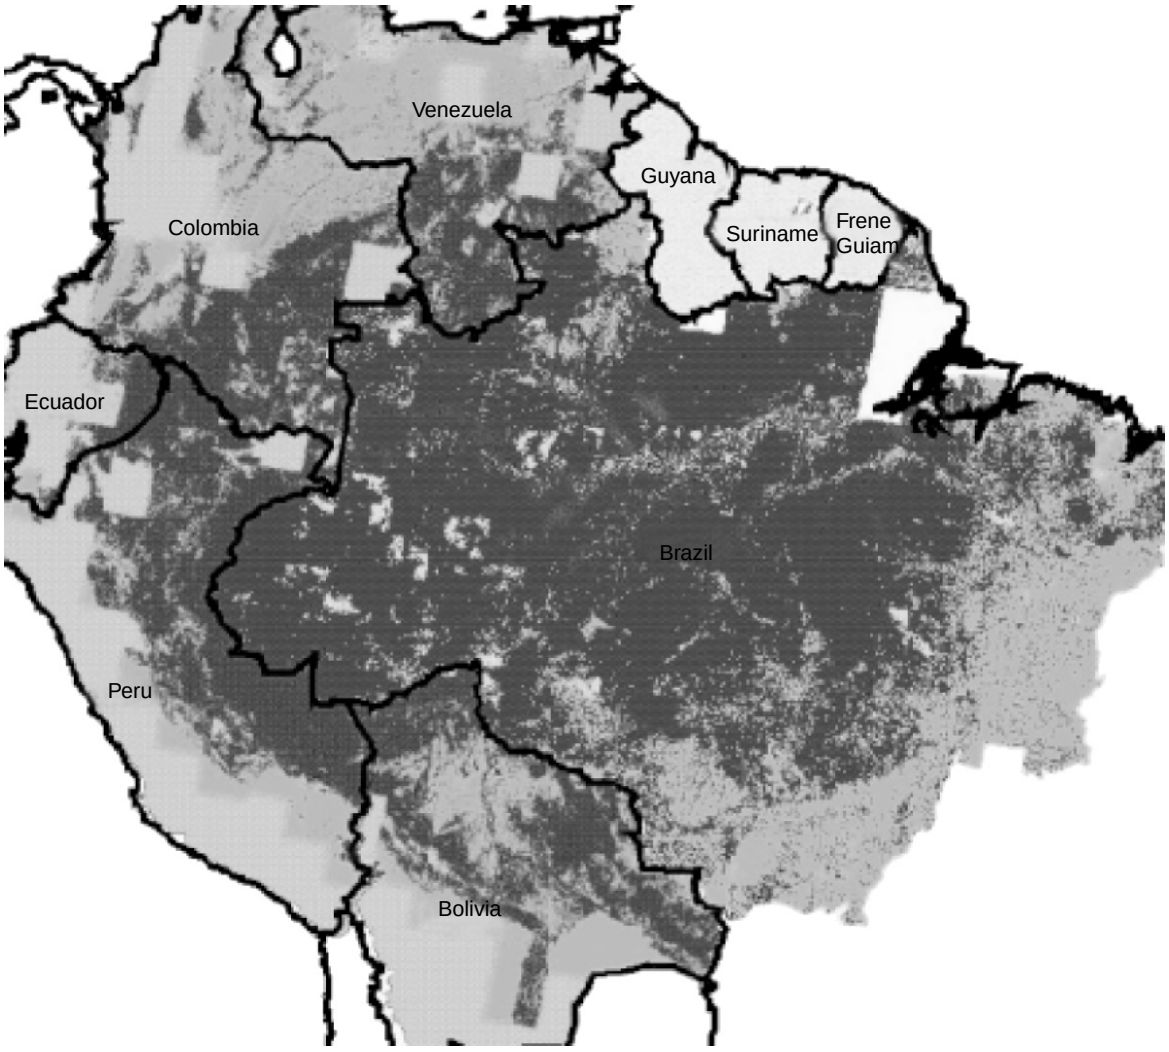

Figure 1 Distribution of Amazonian tropical forest in the early 1990s mapped with Landsat images. This product was produced by the NASA Landsat Humid Tropical Deforestation Mapping Project at the University of Maryland and the University of New Hampshire. Note the degree of fragmentation in the Eastern and Southern part of the basin. Persistent cloudiness has prevented direct observation of forest cover in some areas. Landsat data are still being acquired to fill in gaps caused by cloud interference

Table 1 Estimates of tropical forest area and deforestation for the Amazonian countries. (Data from UMD/MSU are for the Brazilian legal Amazon, and the Amazon basin only in non-Brazilian countries. Data from the FAO are for tropical forest and woodland in areas of • 1000 mm precipitation (FAO, 1993, 1996)

	Tropical forest area (km^2) (FAO)	Deforestation rate (km^2/year) (FAO)	Tropical forest area (km^2) (UMD/MSU)	Deforestation rate (km^2/year) (UMD/MSU)
Country	1990	1980–1990	1992	1986–1992
Bolivia	459 000	5320	426 000	1937
Brazil	4 093 000	36 710	4 093 000	15 200
Colombia	541 000	3670	415 000	883
Ecuador	120 000	2380	51 000	–
Peru	674 000	2710	495 000	1353
Venezuela	457 000	5990	285 400	387

Areas of mature forest, deforestation, young forest regrowth, savanna, water and cloud were mapped and stored in a GIS. Young forest regrowth was treated as deforestation and may constitute 20% to 40% of the total deforestation (Steininger, 1996; Houghton and Skole, 2000). Areas of large-scale deforestation were mapped, as were small clearings associated with indigenous communities, rubber tappers, coca farmers, mining operations, logging camps, airfields, blow-downs, illegal drug operations, and other small disturbances. All visible roads, power line right of ways, pipelines, and similar human-made features were also mapped as deforestation. These data were then merged and joined into a seamless data set for Brazil and the non-Brazilian Amazon Basin (Figure 1). The classification results are supported by field surveys carried out by our team and other research groups in Bolivia, Brazil, Ecuador, and Venezuela.

The largest areas of deforestation, edge-affected and fragmented forest were concentrated in an arc along the southern and eastern fringe of the Amazon Basin, extending from Pará, Brazil southward and westward to Santa Cruz, Bolivia. Deforestation in the interior of the Amazon Basin was closely associated with transportation corridors. Our estimates of deforestation in the Amazon, up to 1992 1993, are lower than other estimates, such as those in the widely cited reports of the Food and Agriculture Organization (FAO) (Table 1; FAO, 1981, 1993, 1996). We are very concerned that Amazonian deforestation is accelerating with the economic integration of the economies of South America. The Santa Cruz, Bolivia area is an example of accelerating deforestation throughout the 1990s, primarily for industrial soybean farming (Steininger *et al.*, 2000b).

The impact of tropical deforestation upon biological diversity is far greater than the deforestation or destruction of habitat *per se*. Our studies show that when edge and isolation effects are combined with actual deforestation, the total area affected negatively for biological diversity increases to two to three times the deforested area (Skole and Tucker, 1993; Steininger *et al.*, 2000b). The preponderance of affected habitat results mainly from proximity to areas of deforestation and not from the isolation of forest fragments. Skole and Tucker (1993) reported a 1988 Brazilian Amazon Basin deforestation of 230 000 km^2, a total 1-km buffer area of the deforestation-forest contact edge of 341 000 km^2, and only 16 000 km^2 of isolated forest fragments. Conversely, in areas of very high deforestation or older settlement histories, the remaining forests are mostly affected by the isolation of fragments (Gascon *et al.*, 2000). It is imperative to minimize both of these kinds of human activities that further fragment large areas of intact tropical forest.

Deforestation in Historic Times

Michael Williams
University of Oxford, Oxford, UK

Deforestation is as old as human occupation of the Earth, controlled fire probably being coterminous with the emergence of Homo erectus some 0.5 million years ago. Taking the long view, tropical forest destruction since circa 1950 is just a blip on an ever-upwardly sloping curve, probably being no more than between 6–7.5% of the total amount of forest ever cleared. Admittedly, compared to previous deforestation episodes, it is more rapid, more detrimental to global biodiversity, and is occurring in more sensitive and irreversibly damaged environments. But it is nothing new; it is part of the age-old quest of humanity for shelter, food and warmth.

The attraction of forested environments is not difficult to understand. Trees provide wood for construction, for shelter, and for making a multitude of implements. Wood provides fuel to keep warm, to cook food and even to smelt metals. The nuts and fruits of the trees are useful for food, medicines, and dyes, and the roots, young shoots and branches provide food for animals. Cleared forest provides land for growing crops – land, moreover, often covered by a deep humus accumulation and initially rich in nutrients. Clearing requires no sophisticated technology. Humans with stone or flint axes need only boundless energy to fell trees; in contrast, fire and browsing animals can wreak havoc in forested areas with little effort. The substitution of metal for stone axes circa 3500 years ago, and then for saws in the medieval period, eased the backbreaking task of clearing, and accelerated the rate of change, but they did not alter the basic process of destruction and land-use transformation. Power-saws during the last 50 years have made a major impact.

*Three basic questions bedevil the history of deforestation, as they do current concerns (Williams, 1994). What exactly is a forest, what constitutes deforestation, and what was the extent and density of trees at any past given time? Although there are many inconsistencies in various official definitions, for present purposes forest is defined loosely as ranging from a closed-canopy tree cover to a more open woodland (*see *Forest: the FAO Definition, Volume 2). Deforestation is taken to mean any process which modifies the original vegetation, from clear-felling, to thinning, to occasional fire. However, it should not be forgotten that forests regrow, often vigorously. The answer to the final question is partially dependent on answers to the preceding two questions. If human history is taken to mean after the last Ice Age (e.g., 10 000 before present (BP)), then the subsequent climatic fluctuations and ice sheet movements during the late Quaternary caused massive shifts in vegetation belts, especially in the middle latitudes. Palynologists have reconstructed the late Quaternary pollen record of the forest at both local and continental scales, but it is still difficult to capture the kaleidoscopic patterns of change in the distribution of trees. Past vegetation is of interest to climatic modelers who are aware of the role it plays in the radiation balance of the earth and in various bio-geochemical cycles related to climatic change. According to Matthews (1983) the pre-agricultural closed forest probably once covered* $46{\cdot}28 \times 10^6$ *km*^{2}, *and more open woodland* $15{\cdot}23 \times 10^6$ *km*^{2}; *these have been reduced by* $7{\cdot}01 \times 10^6$ *km*^{2} *and* $2{\cdot}13 \times 10^6$ *km*^{2}, *respectively. Historical reconstructions of known clearing episodes and potential rates of clearing based on population numbers support the general magnitude of change as being between approximately* $8{\cdot}05 \times 10^6$ *km*^{2}, *and* $7{\cdot}44 \times 10^6$ *km*^{2} *(Williams, 1991). Thus, the total area of forest in the world has possibly decreased by 15.15% and the woodlands by 13.8%, a massive amount to be sure, but not, perhaps the worldwide devastation that is commonly supposed. Further refinement of these figures is unlikely because of the paucity of reliable records. In the past, clearing was regarded as the most natural thing in the world; it was the first step to improvement and agricultural expansion, and almost no one wrote about it or recorded statistics about it.*

PRE HISTORIC CLEARING

Pre-literate societies throughout the world had a far more severe impact on the forests than is commonly supposed because the increase and spread of people took place in largely forested environments. This was true in Europe from the late Mesolithic and certainly during the Neolithic, and also in the far more chronologically and spatially diverse societies of the Americas, from north to south (Williams, 2000). In Europe, Mesolithic cultures did not avoid forests but actively engaged with them. There is evidence of cultivation, clearing and use of fire for game hunting in England in the upland fringes of the Pennines, North York Moors and Dartmoor, and successive clearings are accompanied by the presence of pollens of light-demanding plants, such as sorrel and ribwort plantain, which could only flourish as a result of clearing. The subsequent 3000 years of Neolithic agriculture/settlement was far more sedentary and stable than previously thought. The significance of the widespread incidence of timbered long houses has been ignored, yet many had been occupied for hundreds of years, which makes the previous dominant paradigm of a slash-and-burn economy unlikely. Rather, the Neolithics sought out gently shelving sites on the floodplain-lower interfluve slope zone, favoring loessic soils because of their fertility and not for their supposed treelessness. Flint and stone

axes made short shrift of the forest, and the flood plains were used for intensive garden cultivation and meadows. Cereal crop yields were sustained for surprisingly long periods on these soils, and shortfalls in diet were made-up by a reliance on cattle, which supplied meat, blood, milk and cheese, and sheep and pigs were also present. Consequently, large numbers of livestock were needed to make it economically feasible to extract milk and meat produce. Herds of between 10 and 20 are too small; 30 50 head are more realistic. A typical six-household, 30-person, locationally fixed settlement would have needed to plant 13.2 hectare (ha) of wheat, and run a 40-head herd of cattle with 40 sheep/goats. If the area used for housing, garden plots, a woodlot, constructional timber, pasture land, meadows and rotational forest is totaled up, then each group of 30 persons needed a little over 6 km^2 of woodland to survive, a staggering 20 ha per person (Bogucki, 1988; Gregg, 1988).

Modern experiments show that flint and stone axes were quite capable of being used for forest felling. Burning and animal grazing, if intensive enough, would have thinned and ultimately eliminated forest in other areas. The process continued unabated during the late Neolithic to early Bronze ages (*circa* 3000 1000 BC). Charcoal layers and successive decreases in forest pollens, followed by increases in cereal and weed pollens in peat deposits, together with interbedded farming and clearing implements, leave one in no doubt about the sequence of events. The evidence for similar processes of early forest disturbance with clearing are unfolding for the Americas so that any concept of virgin forests before European contact is a myth (Denevan, 1992). For example, burnings, swiddens (rotational burning and clearing for cropping), and manipulation of trees in the rainforest of equatorial upland areas may date from at least the early Holocene, and most soils are studded with charcoal. That could be due to natural lightning strikes but as these are usually accompanied by abundant rain in tropical areas, then humans must be responsible for most fires in prehistory. Ethnobotanists think that much of the Amazonian forest is a cultural artefact as native peoples have developed successive resource management strategies to cope with fluctuations in population dynamics. Similar arguments can be made for the Maya lowlands and other parts of tropical Central America.

In temperate North America, the vivid descriptions of indigenous clearing and agriculture in 16th and 17th century travel accounts is substantiated by archaeological and palaeobotanical evidence. From at least 12 000 BP the aboriginal population occupied the rich bottom-lands of the many river systems of the continent though they never abandoned hunting. Progressive clearing of the forests on the flood plains and lower terraces, and the intensification of cropping gradually converted the landscape into a mosaic consisting of permanent settlements and cultivated fields, early successional forests invading abandoned old fields, and remains of the original deciduous forest in the uplands (Delcourt, 1987). By 1000 AD, the Indians of the Woodland Culture were colonizing the fire-prone eastern woodlands.

With the exception of the long-settled savanna-woodland and adjacent belts in West Africa, knowledge about deforestation in Africa is sparse, and may well not have happened on a scale sufficient to be recorded. Whether in Europe, Africa, Asia or the Americas, the record is clear. The axe, together with dibble-and-hoe cultivation and later the light plough, often integrated with pastoral activity in Old World situations, reduced the extent of the forest and altered its composition. Fire was particularly destructive. Delcourt (1987) has suggested that early humans produced four major changes:

1. The increased frequency and magnitude of disturbance resulted in the expansion of non-forested patches or clearing.
2. The increasingly sedentary life style, the development of territorial control, and the high energy investment in the cultivation of crops resulted in a new sort of disturbance in which large areas were kept in the early stages of succession, which allowed the invasion of subsequent weed populations.
3. The selective utilization of plants by humans and animals resulted in long-term changes in the dominant tree structures within forest communities.
4. There were substantial changes in the distributional limits of certain species.

The impact of early humans on the forests was greater than suspected, and greater than many would care to admit. It may well have been one of the greatest deforestation episodes in history.

THE CLASSICAL ERA

Although the pre-historical period overlapped with the conventionally labeled classical one there were important differences. From *circa* 3000 BP to the end of the Dark Ages, increasing population, burgeoning urbanization, mineral extraction, and trade by different cultures and civilizations mainly on the northern rim of the Mediterranean basin brought enormous changes in forest vegetation. More importantly, archaeological and palaeoecological evidence is supplemented by a contemporary literature, e.g., the works of Strabo, Theophrastus, Cicero, Varro, and Columella. For the first time, people recorded what they saw, did to, and thought of, their external world and were conscious of their power to control and even create nature. The primary cause of clearing was either to grow food or facilitate grazing, followed in uncertain order by domestic fuel procurement, shipbuilding and

metal smelting. Tantalizingly, the detail of each process comes in roughly reverse order to its importance. Thus, as ever, clearing for growing food gets little mention as it is subsumed into the larger practice of agriculture. On the other hand, metal smelting looms disproportionately large because of the intense local impact, as at Rio Tinto, Populonia, Lauarion, or Cyprus, although it is doubtful if it was as devastating as it is commonly made out to be. The image of the industrious ploughman who subdued his woodland with flames and plough and who carted off the timber he had felled was common enough. And there were many references to extensive forests, e.g., at Avernian in Campania or the impassable and appalling Ciminian Forest of Southern Tuscany, that had either been vastly diminished or eliminated. But evidence is more abundant about felling to smelt metal or to produce fuelwood for domestic use and baths, to service the general timber trade to Imperial Rome and other cities, as a result of warfare, and particularly through shipbuilding by Venetian and Arab traders during the 7th to 11th centuries AD (Meiggs, 1982; Thirgood, 1981). The marked seasonality of the climate, the prevalence of fire and overgrazing by stock, particularly goats, resulted in the succession to an inferior woodland garigue or marquis which in turn could be degraded to poor pasture. Ultimately, massive erosion with associated deposition in almost tideless coastal locations, led to expansions of wetlands and the widespread onset of malaria by the fourth century BC. Centuries of overgrazing and clearing during the medieval period continued the process.

A general picture emerges of considerable change, but caution is needed not to over-state the extent of forest degradation and erosion or their contribution to economic decline. With a few exceptions, forests furnished the timber needs of the time and in the early Renaissance period, as evidenced by the great fleets launched in Venice, Genoa and Catalonia built from abundant, though diminishing, forests. It is likely that the ultimate denudation of the Mediterranean world came much later and was the product of population pressure during the 19th and early 20th centuries.

THE MIDDLE AGES

The Middle Ages, particularly in Europe, but also in China, witnessed a surge of economic activity in which the forest and its multiple riches played a central part. The extent of the forest clearing in the European continent is not known but it has been suggested that the forests of France were reduced from 30×10^6 ha to 13×10^6 ha between *circa* 800 and 1300 AD, (Bechmann, 1990) and still a quarter of the country was covered, while in Germany and Central Europe, perhaps 70% of the land was forest covered in 900 AD and about 25% remained by 1900 AD (Schluter, 1959), the high point of clearing occurring between 1100 and 1350 AD. The cultural climate of the age was crucial to understanding events. There was an intense religious belief in creating a divine, designed earth, coupled with a need to understand and use nature for practical ends. Lay and ecclesiastical owners cleared vast areas both for the glory of God and personal territorial gain; piety was accompanied by zeal (Glacken, 1967). The driving change was a six-fold increase of population between 650 and 1350 AD. Under-utilized and marginal lands were colonized in the west European heartland, and a massive expansion of settlement occurred in the forests of central and Eastern Europe.

In order to avert famine amongst the burgeoning population, food production needed to increase. Three technical innovations aided this. First, the dominant two-fields with one fallow was replaced by a three-field system, thus shortening the fallow period. This was possible because new crops like oats and legumes helped to fertilize the soil and added to animal and human nutritional requirements. Secondly, the development of the wheeled plough with coulter and mouldboard allowed cultivation to move from light soils onto heavy moist soils that were usually forested. Thirdly, ploughing efficiency was improved by the invention of the rigid horse collar and nailed horseshoes, both favoring the horse over the ox by increasing the speed and pulling power. Whereas the old manorial system was solidified, custom-bound and socially immobile and stratified, the new clearing and expansion produced a more fluid society. Aggrandizing landlords encouraged new settlers onto their lands, and offered generous terms of ownership, disposal and personal freedom, so that clearing contributed in a general way to the emancipation of the common man. This spectacular expansion is the subject of a vast literature. Place names indicating clearing and new settlements in forested areas abound, and rent rolls, charters, and leases show how expansion occurred. Pollen evidence is also useful.

These data show that cultivation expanded from about 5% of land use in the 6th century AD to 30 40% by the late Middle Ages, and the vast tracts of forest were fragmented, thinned or eliminated. It was also an age of organized colonization of the frontier by Germanic settlers into central and Eastern Europe, a thrust, which changed the ethnic and settlement map of that part of the continent. By the end of the 12th century the reduction of forest cover and the rise of personal power by the nobility led to their exerting territorial control on the remaining forests as hunting grounds. This was opposed by the peasants who gathered fuel, grazed stock and made good use of the forest products. The vast body of custom and rights that grew up subsequently to govern the use of the forest was a measure of its increasing scarcity. The various elements interlocked to produce what White

(1962) has called the agricultural revolution of the Middle Ages which asserted the dominance of humans over nature and shifted the focus of Europe from south to north, from the restricted lowlands around the Mediterranean to the great forested plains drained by the Loire, Seine, Rhine, Elbe, Danube and Thames. Here the distinctive features of the medieval world developed a build-up of technological competence, self-confidence, and accelerated change which, after 1500 AD, enabled Europe to invade and colonize the rest of the world. In that long process of global expansion, the forest and the wealth released from it played a central part.

Little is known about clearing in China where massive change to the forests must have happened also. There is a paucity of information on peasant life and livelihood, but an abundance of data on the working of bureaucratic government (Murphy, 1983). The detail of agricultural clearing is murky, but the demands of industry are clearer. A flourishing iron and steel industry in the Shantung region in Northeast China during the Northern Sung (910 and 1126 AD), and the early substitution of coal for charcoal suggest not only precocious technological development but widespread devastation and shortages of fuel. By roughly 1078 AD, production was about 125 000 150 000 tons, only a little less than total European production at the beginning of the 18th century (Hartwell, 1966). Then production declined by a half, whether through exhaustion of fuel, the Mongol invasions, or some other factor, is not known.

EARLY MODERN TIMES

The 450 years from 1492 *circa* 1950 AD are characterized by dramatic and well-documented terrestrial transformations. Europe burst through the confines of the continent with devastating consequences for the forests of the rest of the world. The previous largely land-based civilizations were now replaced by an inter-continental one and the creation of a global economy. The ecological imperialism (Crosby, 1986) of weeds, animals, diseases and ultimately people, that very largely began with Columbus in 1492 AD, ravaged the neo-European world. New economic and social systems were imposed or grafted on to existing societies. The European capitalistic economy commoditized nearly all it found, creating wealth out of nature, whether it was land, trees, animals, plants or people. This radical change occurred against a background of a steadily increasing world population (up more than six-fold from just over 400 million in 1500 AD to nearly 2.5 billion in 1950 AD: and before 1900 AD, most of this increase occurred in Europe). Additionally, rising rates of consumption for raw materials and food with urbanization, agricultural change and industrialization, first in Europe and, after the mid-19th century, in the US and Canada, put even greater strains on the forest resource. In the sparsely settled and mainly temperate areas, neo-European societies were planted and created. After an initial period of near elimination of the indigenes by virulent Old World pathogens, particularly smallpox after 1518 AD, followed by the triumph of Old World crops and stock, permanent settlement began in earnest by the mid-17th century. Although accompanied by much environmentally destructive exploitation the virtues of agriculture, freehold tenure, dispersed settlement, improvement and personal and political freedom were extolled, which all led to a rapid and successful expansion of settlement. Tree growth was considered a good indicator of soil fertility in all pioneer societies, and consequently the bigger the trees, the quicker they were felled to make way for farms. The US was the classic example of this neo-European clearing for agriculture with about 60 000 km^2 being felled by about 1850 AD and a further 660 000 km^2 by 1910 AD (Williams, 1989). It was one of the biggest deforestation episodes ever. Clearing was a combination of sweat, skill and strength and the pioneer farmer on the frontier was seen as the heroic subduer of a sullen and untamed wilderness. Clearing was widespread, universal and an integral part of rural life; and continued well into the early years of the 20th century. The French traveler, the Marquis de Chastellux marveled that;

> Such are the means by which North America, which 100 years ago was nothing but a vast forest, is peopled with three million of inhabitants. Four years ago, one might have traveled 10 miles in the woods I traversed, without seeing a single habitation.
>
> (Chastellux, 1789)

But it was not only the US where the archetypal image (and reality) prevailed of the single pioneer hacking out a life for himself and family in the forest. There were other parts of the world such as Canada, New Zealand, South Africa and Australia where similar pioneer clearing occurred. In Australia, for example, perhaps a total of another 400 000 km^2 of the southeastern forests and sparse woodland were cleared by the early 20th century (Williams, 1988). In the subtropical and tropical forests, European systems of exploitation led to the harvesting of indigenous tree crops (e.g., rubber, hardwoods), but also to the replacement of the original forest by crops grown for maximum returns in relation to the labor and capital inputs, often in a plantation system and often, too, either with slave or indentured labor. Classic examples of this were the highly profitable crops of sugar in the West Indies; coffee (green gold), and sugar in the subtropical coastal forests of Brazil, cotton and tobacco in the southern US, tea in Sri Lanka and India, and later rubber in Malaysia and Indonesia. All flourished at the expense of the forest. In Eastern Brazil, perhaps over half of the original 780 000 km^2 of the vast subtropical forest that ran down the eastern portions of the country had disappeared by 1950 through agricultural exploitation

and mining. In the state of Sao Paulo alone, the original 204 500 km^2 of forest was reduced to 45 500 km^2 by 1952 (Dean, 1995).

A variation of this agricultural clearing occurred in Southern Asia where peasant proprietors were drawn into the global commercial market. Outstanding was the deliberate expansion of rice cultivation in lower Burma by British administrators which resulted in the destruction of about 90 000 km^2 of rain forest between 1850 and 1950. Throughout the Indian subcontinent, the early network of railways meant an expansion of all types of crops, often for cash, that led to massive forest clearing in all parts of the country (Richards and McAlpin, 1983). The European impacts were not the only ones. Traditional societies often exploited their forests vigorously in a manner no more egalitarian or caring than those affected later by European commercial influences. There is plenty of evidence from, e.g., Southwest India and Hunan province in China (Perdue, 1987) from the 16th century onwards, that the commercialization of the forest was not a European invention. In pre-British Southwest India, permanent indigenous agricultural settlement existed side by side with shifting cultivation, and village councils regulated how much forest exploitation could be undertaken by agriculturalists. The forest was not regarded as a community resource; larger landowners dominated forest use in their local areas. Scarce commodities such as sandalwood, ebony, cinnamon, and pepper were under state and/or royal control. In Hunan, in south Central China, a highly centralized administration encouraged land clearance in order to enhance local state revenues so as to increase the tax base and support a bigger bureaucracy and militia. Later migrations into the forested hill country of South China were also encouraged by the state.

Simply, forests everywhere were being exploited and were diminishing in size as a response to increasing population numbers and increasing complexity of society. In the subtropical world, the changes came later than those unleashed by the Europeans with their new aims, technologies, and intercontinental trade links, but no less severe. In all, as much as 216 000 km^2 of forest and 62 000 km^2 of interrupted or open forest were destroyed in South and Southeast Asia for cropland between 1860 and 1950 alone. However, in focusing on distant lands and on the overseas expansion of Europe, one should not forget that Europe itself was being colonized internally during these centuries (Darby, 1956). This was particularly true in the mixed forest zone of central European Russia where over 67 000 km^2 were cleared between the end of the 17th century and the beginning of the 20th century (French, 1983). The insatiable demand for new land to grow crops and settle new societies in all ages has been matched by a rising demand for the products of the forest themselves. For example, the quest for strategic naval stores (masts, pitch, tar, turpentine) and ships timbers made major inroads into the forests of the Baltic littoral from the 14th century onwards and from the southern states of the US after about 1700 AD (Albion, 1926; Lower, 1973). Alternative construction timbers like teak and mahogany were discovered in the tropical hardwood forests after circa 1800 AD.

THE 20TH CENTURY

The pace of transformation increased during the first half of the 20th century. In the Western world, demands for timber accelerated. New uses (pulp, paper, packaging, plywood, chipboard) and relatively little substitution of other materials made timber a crucial resource in energy production, construction and industry generally. It had a strategic value akin to that of petroleum today. Agricultural clearing experienced a downturn with the abandonment of difficult, hard-to-farm lands and a concentration on easier-to-farm open grasslands. Consequently, farmland actually reverted to forest in the eastern US and Northern Europe, leading to a declining net loss of forest. In the tropical world the massive expansion of population by more than half a billion from a base of 1.1 billion resulted in extensive clearing for subsistence, accompanied by an expansion of commercial plantation agriculture. In all, perhaps 235×10^6 ha of tropical forest were lost from 1920 1949.

But the big changes occurred after 1950. While the temperate coniferous softwood forests have just about kept up with the demands of industrial societies for abundant supplies of timber and pulp, the focus of deforestation has shifted firmly to the tropical world. Better health and nutrition has resulted in a population explosion. These often landless-people have moved deeper into the remaining forests and farther up steep forested slopes, often with serious erosional consequences. They have little security or stake in the land and therefore little commitment to sustainable land management. Since 1950 about 550×10^6 ha of tropical forests have disappeared. In addition, the tropical hardwood forests are also being logged-out for constructional timber at an alarming rate, while wood is cut for domestic fuel in prodigious quantities in Africa, India and Latin America. In total cubic terms globally, fuelwood now roughly equals saw-timber extraction about $1{\cdot}8 \times 10^9$ m^3 compared to $1{\cdot}9 \times 10^9$ m^3, and it is forecast to rise rapidly in line with the increasing world population (Eckholm, 1975; Williams, 1991). It is probable that 2 432 000 km^2 of forest was cleared between 1860 and 1978, together with 1 502 000 km^2 of more open woodland (Richards, 1986, 1991).

CONCLUSION

The topic of deforestation is vast and complex, and is no less than a sizeable portion of world history. Many

more regional examples of deforestation from all ages could be cited. Nevertheless, the continuity of the process is striking. Forest clearing is one of the main causes of terrestrial transformation whereby humankind has modified the world s surface, a process, which is now reaching critical proportions (Williams, 1990). Whatever the detail, one thing is certain; with an ever-increasing world population, the process of deforestation will not end in the future. For those living in or near the tropical forest, it will continue to provide land, fuel and shelter for as long as the forests last, and be the mantle of the poor. Many will want to exploit its abundant timber resources while others will continue to restrict its use and preserve it. The tensions between exploitation and preservation will continue.

Deforestation, Tropical: Global Impacts

John H C Gash
Centre for Ecology and Hydrology, Wallingford, UK

Tropical rainforest is typi ed by a dense, continuous canopy stretching up to above 30 m in height, with a great variety of species. It is found in the humid tropics where the dry season is no more than about four months and at other times the rainfall is plentiful. Although rainforest is the world's most luxuriant vegetation, it grows on some of the poorest soils. Most of the nutrients are in the biomass and there is rapid recycling of nutrients from the soil into the vegetation, through the dense mat of roots just below the leaf litter layer. Rainforest also has deep roots, down to below 10 m in some cases, which allow the forest to continue transpiring through the dry season. Where the soil is not deep enough to maintain transpiration through the dry season, rainforest gives way to dry season deciduous, savanna forest.

When rainforest is replaced by agriculture, there are changes to the energy and water balances: less solar radiation is absorbed and more infrared radiation is emitted. The way in which that radiative energy is divided between evaporating water, and heating the air, also changes. Deforestation creates a more extreme local climate with higher daytime and lower nighttime temperatures. If there is large-scale deforestation, this may result in changed weather patterns and climate. Predictions are that large-scale deforestation will reduce rainfall.

Forest soils are very permeable, but deforestation using mechanized extraction techniques and heavy machinery, or continued trampling by cattle after deforestation will compact the soil, increasing the surface run-off and resulting in soil erosion. Deforestation will almost always make river ows increase more rapidly in response to storms, with a greater likelihood of ooding.

After fossil fuel combustion, destruction of rainforest by burning is the second largest contributor to the build-up of atmospheric carbon dioxide. However, the remaining rainforest is estimated to be a net sink for carbon dioxide. The forest takes up carbon dioxide during photosynthesis, but gives it out during respiration, as when vegetation dies and decomposes. The difference between these two uxes is small, and in dry years the forest may be a net source of atmospheric carbon dioxide.

Recognition of the economic value of rainforest both as a sink of carbon and a source of biodiversity may lead to changes in governments' policies on deforestation, but these will only be effective if it becomes more economically attractive for the local population to maintain the forest than to remove it.

INTRODUCTION

Tropical Rainforest

Tropical rainforest is a term commonly used to cover a range of forest types occurring in the humid, Equatorial belt across South and Central America, Africa and South-east Asia. The rainforest is typified by a dense continuous canopy, stretching to above 30 m in height, with a great diversity of plant species, the majority of which are evergreen. Tropical-moist-forest is a more precise definition of this range of biomes, since true rainforest occurs only in areas where there is no dry season and the rainfall is always greater than about 100 mm per month. The forest can extend to areas where there are dry seasons of up to four months, but where the dry season is longer, the rainforest gives way to dry savanna-type vegetation. Here we follow common usage, so that the word *rainforest* applies to the whole range of tropical moist forest (*see* Tropical Forests, Volume 2).

Rainforest Soils and Roots

The paradox of tropical rainforest is that it is the world s most luxuriant vegetation, but that it is growing on some of the world s poorest soils. The soils of the Equatorial tropics are generally low in nutrients and organic matter but the forest has evolved to optimize the use of the available nutrients. This is done so efficiently that almost all nutrients are held in the biomass itself. Recycling of nutrients in the forest is rapid: the high temperatures and humidity, and large insect population promote fast decomposition of fallen leaves or other dead vegetation, and the soil surface is covered by a dense mat of roots which intercepts the nutrients as they are released. The lack of nutrients in rainforest soils often results in deforestation leading to unsustainable agriculture, which is abandoned after a few years. There are also very deep roots, which have been observed at depths below 10 m (Nepstad *et al.*, 1994). These deep roots give the forest access to a store of soil moisture that enables it to survive the most severe dry seasons without significant water stress (Hodnett *et al.*, 1996a,b).

Evaporation from Rainforest

Annual evaporation from tropical rainforest is between 1000 and 1500 mm. Rain falling on to the forest canopy is intercepted and some 10 15% of it evaporates rapidly back into the atmosphere (Lloyd *et al.*, 1988). The rain which is not intercepted reaches the soil and some is later taken up by the roots to evaporate through the leaves in dry conditions (transpiration). Tropical rainforest is typified by a lack of seasonality in evaporation, with little evidence of any reduction in transpiration due to water

stress during dry season drought: rather the forest relies on a strategy of deep roots to access a large volume of stored soil water, which it uses to maintain transpiration. Where the soil is not deep enough to maintain transpiration through the dry season, the rainforest gives way to dry season deciduous savanna forest. The rapid evaporation of intercepted rainfall and the continuous transpiration results in a significant recycling of water vapor over continental rainforest: it is estimated that some 50% of the rain falling in central Amazonia originates from water evaporated by the forest. It is predicted (see below) that deforestation can disrupt this recycling process and result in a reduced rainfall.

DEFORESTATION

Deforestation occurs at several levels: complete clearance for agriculture, multiple clearance of small plots leading to forest fragmentation, or selective logging of valuable species. Large cleared areas can be detected by remote sensing. Detecting small clearance or selective logging is more difficult, but official statistics and socio-economic data can also be used to derive estimates of deforestation. Deforestation rates estimated by the Food and Agriculture Organization (FAO) are shown in Table 1. Current deforestation is not uniformly spread about the tropics, and there are still vast, remote areas where non-existent communications and lack of access to markets have protected the forest from settlement or exploitation. Deforestation is generally concentrated in hot spots, which usually follow a sequence of road building, migration, and clearance. Rondonia, in the southwest of Brazilian Amazonia, and Kalimantan, in Indonesia, are examples of hot spots with current high deforestation rates. However, in the central African countries bordering, and within, the Congo basin, there is relatively little migration and so far road building has resulted in selective logging rather than clear felling.

The increased human activity in logged or fragmented forest increases the incidence of fire. This risk is exacerbated by the open canopy of this type of forest: greater penetration of the wind into the lower canopy causes the vegetation to dry out during dry weather, making the forest more vulnerable to fire. Deforestation is also caused by flooding of reservoirs behind hydroelectric dams, by mineral extraction, not simply the extraction itself, but also the removal of forest to provide charcoal for smelters and by small-scale removal of wood for fuel to dry crops and for cooking.

CLIMATE

Replacing rainforest by agriculture changes the surface radiation and water balance. These changes affect the local climate, but they also have the potential to affect the thermodynamics and the dynamics of the atmosphere at larger scales and therefore change the weather and the climate.

The Radiation Balance

Albedo is the proportion of the solar radiation falling on the Earth s surface, which is reflected. Because forest is efficient at trapping radiation in its deep canopy, forest albedo is low when compared to agricultural land (Gash and Shuttleworth, 1991; Culf *et al.*, 1996). Typically rainforest has an albedo of about 13%, whereas pasture on deforested land has an albedo of about 18%. In addition to solar radiation, the surface receives long-wave, infrared radiation from the atmosphere and also emits it as black body, thermal radiation. The amount of long-wave radiation emitted depends on the temperature of the forest, but, because of the greater turbulence of the air over the forest, its surface temperature is close to that of the air. The surface of short agricultural crops is not so efficiently cooled and will be hotter than the forest s; this higher temperature results in greater long-wave emission. Agricultural land thus reflects more solar and emits more long-wave radiation than forest, resulting in about 10% less net radiation being available at the surface (see Figure 1).

Local Climate

The climate on the forest floor is largely decoupled from the atmosphere above: temperatures are lower than in the

Table 1 The area of remaining tropical forest in 1995, and its annual rate of change (from: State of the World's Forests. 1997, FAO, Rome)[a]

Region	Area of forest in 1995 Thousand km^2	Average annual change, 1990–1995	
		Thousand km^2 year^{-1}	% year^{-1}
Tropical Asia	2797	−31	−1.1
Tropical Africa	5049	−37	−0.7
Central America and Caribbean	241	−6	−2.2
South America	8279	−47	−0.6

[a] For comparison the area of Belgium is 31 000 square kilometers.

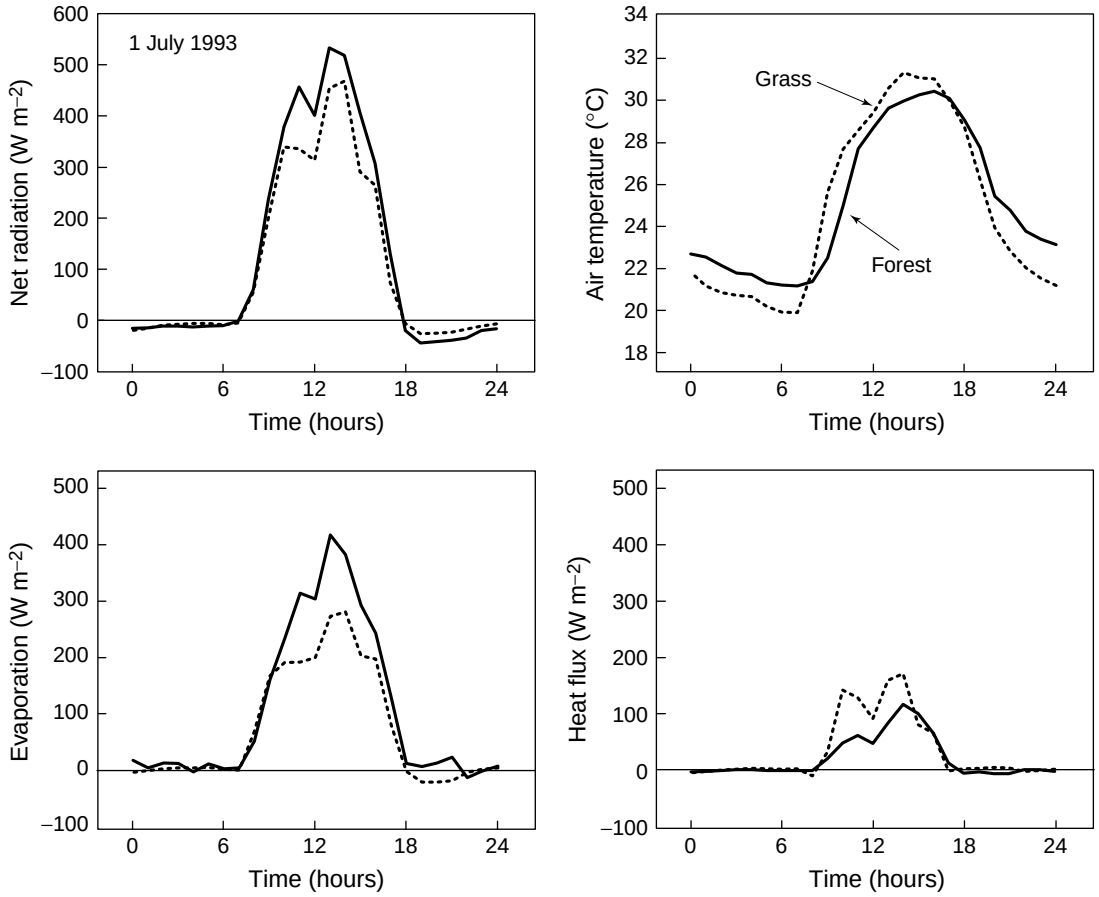

Figure 1 Hourly net radiation, air temperature and the fluxes of evaporation and sensible heat at forest and pasture sites in Rondônia, in Southwest Amazonia, for an example day in the dry season. (Reproduced by permission of the American Meteorological Society from Gash and Nobre, 1997)

air above the forest canopy, but the absolute humidity is slightly higher, giving a much higher relative humidity (Shuttleworth *et al.*, 1985). It is this high relative humidity, coupled with very low wind speeds, that gives the characteristically uncomfortable rainforest conditions. The large biomass of the forest acts to smooth out the daily temperature cycle (see Figure 1). Energy is stored in the biomass during the day and given out at night, so that daytime temperatures are lower over the forest than over deforested land, but at night the forest is warmer.

Evaporation and Sensible Heat Flux

The net radiation at the surface is used for both evaporation and sensible (convective) heating of the atmosphere. Agricultural crops and pasture have shallower rooting depths than forest and can rapidly deplete the store of soil moisture available to them during drought (Wright *et al.*, 1992). Evaporation is then reduced and more energy goes into sensible heat flux. Despite the greater net radiational energy available to the forest, low evaporation from water-stressed pasture can lead to the sensible heat flux from the pasture being greater than that from the forest (see Figure 1).

Regional Climate

At night the land surface is cooler than the atmosphere above and there is a stable boundary layer; but after dawn the surface heats up and convective turbulence develops resulting in a well-mixed boundary layer growing from the surface upwards. The greater the sensible heat flux from the surface, the higher is the top of the convective boundary layer, which may grow up to several kilometers in height. When the height is greater than the condensation level, water vapor in air rising from the surface condenses to form cumulus clouds. Observations of dry season boundary-layer growth taken in Rondonia, in Southwest Amazonia (Nobre *et al.*, 1996) have shown that the differences in sensible heat flux between a large area of forest and a large area of deforestation (more than 50 km across) can result in differences of boundary-layer height of between 700 to 1000 m. Satellite observations of the same area

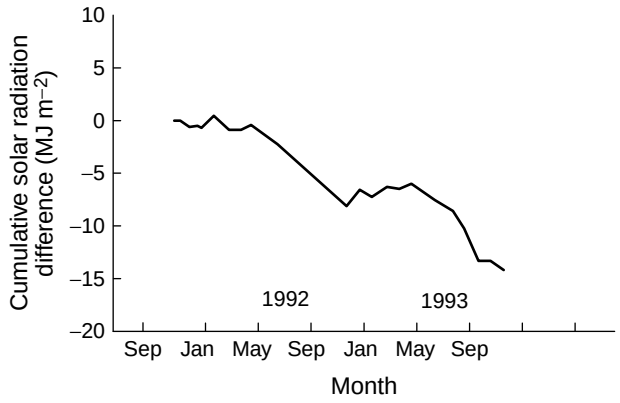

Figure 2 The observed difference in incoming solar radiation between pasture and forest plotted cumulatively for a pair of sites in Rondônia, in Southwest Amazonia. During the dry season (July, August and September) systematically less radiation is received at the pasture site than at the forest. (Reproduced by permission of the Centre for Ecology and Hydrology, redrawn from Culf *et al.*, 1996)

showed differences in cloudiness, with greater cloudiness being observed over the deeper boundary layers associated with the deforestation. This difference in cloudiness was confirmed by observations of systematically lower values of solar radiation reaching the surface shown in Figure 2 (Culf *et al.*, 1996). It is rare to find such convincing, direct evidence that changes in the land surface can affect climate at this regional scale.

Continental and Global Climate

Energy exchange between the land surface and the atmosphere is much greater in the tropics than in temperate latitudes, and it is largely this zonal difference which drives the global atmospheric circulation. Deforestation changes the amount of radiative energy absorbed, and changes the partitioning of that energy between evaporation and sensible heat flux. Just as large-scale changes in sea surface temperature (such as El Nino) can affect global weather patterns, so it might be expected that large-scale deforestation in the tropics could also change the global atmospheric circulation. However, no observational evidence of the effects of deforestation on climate at a continental scale has yet been found. Although there is a wealth of circumstantial evidence pointing to decreased rainfall, rigorous statistical analysis of rainfall records from 48 sites in Amazonia showed almost equal numbers of increasing and decreasing trends (Dias de Paiva and Clarke, 1995). An alternative to observations is provided by modeling studies performed with global circulation models (GCMs). These can be used to simulate the change in climate, which might result from deforestation on scales which have not yet occurred.

GCMs are essentially weather forecasting models, but instead of being used to forecast the weather a few days in advance, they are run for years ahead: first as a control with current conditions and then again with, for example, the land surface in the model having been changed from forest to pasture. Deforestation experiments have been one of the most common uses of GCMs and experiments have been carried out over the past two decades using increasingly realistic models. Most of these have modeled the complete deforestation of Amazonia (e.g., Lean *et al.*, 1996) and almost all have concluded that the deforestation would result in less rain falling over the region. Perhaps more seriously, the models also predict less rain over the adjacent savanna belt and the semi-arid region of Northeast Brazil, which are already prone to serious droughts. Only a few studies have modeled the complete deforestation of all the world s tropical rainforest, but the predicted effect of deforestation is almost always to reduce rainfall over the area that was previously forested (McGuffie *et al.*, 1995). The predicted changes over Amazonia are more than over Southeast Asia and Africa, because the climate in Amazonia is less subject to oceanic influence. Sea surface temperatures and weather patterns in middle and high latitudes have also been demonstrated to be sensitive to global tropical deforestation, but at present it is not possible to come to firm conclusions about the likely size or extent of the changes in global climate which might occur.

HYDROLOGY

One of the most immediate and often most damaging environmental impacts of deforestation is that which can occur to the local hydrology (see Bruijnzeel, 1996). However, the effects are variable, depending on the methods of deforestation used and on the use to which the land is subsequently put. Well-managed removal of forest on good soil, with suitable measures to protect the soil during and after the removal of the timber, can result in successful and sustainable reuse of the land (Critchley and Bruijnzeel, 1996). Unfortunately it is often the case that forest on inappropriate, fragile soils is cleared using techniques that result in long-term damage to the soil structure.

Soil Properties and Erosion

Removing the tree cover does not, in itself, result in greater soil erosion. The impact of raindrops falling on the ground is not made more damaging by removal of the tree canopy. Drops of intercepted rain dripping from the forest canopy reach their terminal velocity in the distance between the top of the canopy and the forest floor and arrive with the same potential to erode the soil as they have in the open. The soil erosion occurs when the protection of the litter, and dense root mat beneath it, is removed and the soil is then exposed to the impact of raindrops (*see* Soil Deterioration and Loss of Topsoil, Volume 3).

Forest soils are generally highly conductive to water flow; even clay soils which normally have low conductivity are full of large pores created by roots and animal activity. This structure may persist after deforestation, below the surface layer of soil, but compression of the soil by machines during extraction of timber, or later by grazing animals, leads to permanent compaction, which reduces the ability of the surface soil layer to conduct water (Tomasella and Hodnett, 1996). This decreased conductivity prevents water infiltrating into the soil and results in water running off the surface, with consequent erosion. Bulldozers and other heavy machinery are particularly damaging to the forest soils and, because there is never frost to break up the soil, this damage persists. Soil erosion is not only a loss of a natural resource for agriculture and forests, it also results in sedimentation of rivers and reservoirs downstream.

River Flows

The greater infiltration of water into forest soils introduces a time lag into the water pathway, so that deforestation will almost always increase the speed of hydrological response, i.e., river flows will increase more rapidly in response to storms, with a greater likelihood of flooding. The reduced evaporation from deforested land (see above) will result in more water being available for river flow. However, this may not always result in increased base flow during dry periods, as the higher runoff in response to storms can reduce the recharge to the groundwater to such an extent that base flow is reduced (see Bruijnzeel, 1996). In temperate latitudes, catchment monitoring has shown that, generally, river flows slowly return to their pre-deforestation patterns if the forest is allowed to re-grow; in the tropics this depends on the care taken to prevent soil compaction during extraction of the timber (*see* Forest Logging Systems in Tropical Countries: Differential Impacts, Volume 3). In general, the humid tropics are not short of water, but decreased base flow can impact water resources used for generating hydroelectricity and, on large rivers, can affect navigation.

At present, the effects of total deforestation on large river basins, such as the Amazon or Congo, cannot be predicted with any confidence. With no change in rainfall, deforestation is expected to result in increased river flow, but negative feedback from the surface to the climate (see above) is expected to reduce the rainfall, thereby reducing runoff. The sensitivity of the system to evaporation is demonstrated by a modeling analysis, which predicted that removing the forest from Amazonia would increase the river flow at Obidos (the last gauging station before the sea on the main channel of the River Amazon) by 21% (Costa and Foley, 1997). The Amazon and the Congo are the major sources of freshwater into the Atlantic Ocean and changes of this magnitude could result in significant impacts on the ocean circulation and therefore climate. The experiments to simulate what these effects might be have not yet been done.

THE CARBON BALANCE

Deforestation as a Source of Atmospheric Carbon Dioxide

It is estimated that some 50% of the world s biomass is stored in tropical forest. The above-ground biomass is about $150\,t\,C\,ha^{-1}$ (tones of carbon per hectare); there are few measurements of below-ground biomass, but it is probably in the range $35\ \ 50\,t\,C\,ha^{-1}$ (see Grace *et al.*, 1999). In comparison, the biomass of pasture or any agricultural crop will be only a few percent of this amount. When forest is burnt, much of the carbon previously stored in the biomass is converted to atmospheric carbon dioxide. Deforestation is second only to the combustion of fossil fuel in contributing to the increase of atmospheric carbon dioxide and the consequent global warming. Fossil fuel combustion and cement production, combined, are estimated to produce 5.5 Gt per year of carbon dioxide and the net emissions from changes in tropical land-use 1.6 Gt per year (Houghton *et al.*, 1996).

Tropical Forest as a Sink for Atmospheric Carbon Dioxide

During photosynthesis, vegetation takes in carbon dioxide and gives out oxygen: this has led to the tropical forests being described as the lungs of the world. However the description is simplistic, because the process of respiration, largely the decomposition of dead organic matter, gives out carbon dioxide, balancing most, sometimes perhaps more than, that taken in by photosynthesis. The net carbon dioxide budget (or net ecosystem production) is the balance between photosynthesis and respiration, and is a small difference between two large numbers.

The net carbon dioxide flux can be measured in the turbulent lower atmospheric boundary layer above the forest canopy, using the eddy correlation method. In this method, measurements of vertical wind speed are correlated with measurements of carbon dioxide concentration: when upward moving air is correlated with an increase in carbon dioxide concentration, there is an upward flux of the gas and *vice versa*. Measurements must be taken rapidly (at a frequency of greater than 20 Hz is best) to measure the flux transported by high frequency turbulence. The method has been used at two sites in Amazonia (Grace *et al.*, 1995; Mahli *et al.*, 1998) and both sites were found to be sinks for carbon dioxide. In central Amazonia, annual rates were estimated to be $30\,t\,C\,ha^{-1}\,year^{-1}$ of photosynthesis and $28.1\,t\,C\,ha^{-1}\,year^{-1}$ of respiration, making the forest a net

Table 2 The estimated net annual carbon fluxes between the atmosphere and undisturbed Amazonia, in response to interannual climate variability and increasing CO_2 concentration (SD is the standard deviation)[a]

Year	Net carbon uptake Pg C year^{-1}	Year	Net carbon uptake Pg C year^{-1}
1980	0.3	1988	0.1
1981	0.7	1989	0.3
1982	0.1	1990	0.3
1983	−0.1	1991	−0.1
1984	0.5	1992	−0.2
1985	0.2	1993	0.7
1986	0.4	1994	0.3
1987	−0.2	SD =	0.3

[a] Negative fluxes indicate Amazonia was a net source of CO_2. (Data from Tian *et al.*, 1998).

sink of 2.3 t C ha^{-1} year^{-1} (Grace *et al.*, 1999). However, the measurement of nighttime fluxes with this method is problematic and the result is sensitive to the treatment of nighttime data (Culf *et al.*, 1999). These figures may thus be overestimates, although analysis of tree growth data (Phillips *et al.*, 1998) also shows accumulation of carbon by tropical forest.

Net carbon dioxide flux is the small difference between photosynthesis and respiration, and because these fluxes must be estimated with quite different models, it is difficult to model the net carbon flux to any worthwhile absolute accuracy. However, models can be used to extrapolate measurements in time (as was done to derive the annual estimates above) or to look at the sensitivity of the carbon balance to change. Photosynthesis varies with climate whereas respiration varies primarily with the temperature of the biomass and soil. Photosynthesis is also expected to increase with ambient carbon dioxide concentration. Table 2 shows how this sensitivity translates into variability in estimated annual net carbon uptake. Using a terrestrial ecosystem model, the net carbon flux of the whole of the Amazonian rainforest is estimated to vary between being a sink of 0.7 Pg C year^{-1}, to being a source of 0.2 Pg C year^{-1} (Tian *et al.*, 1998). The latter years were associated with dry conditions following El Nino events.

ECONOMICS

Generally the market value of rainforest as a whole is low, and its benefits non-marketed and little understood. Conventional investment appraisal techniques are, therefore, more likely to result in development options being interpreted more favorably than a non-development alternative. For example, economic calculations may show that it is beneficial to flood vast areas of forest to build hydroelectric power stations, even though these power stations are very inefficient in terms of the flooded area needed to generate a given amount of electricity. Similarly if the land is producing nothing of commercial value as forest, an economic cost benefit analysis will show that it is beneficial to convert the land to agriculture, however inefficient that agriculture may be. The principles of Ecological Economics challenge the established notion that the value of the environment can be equated with market prices in this way and seek to quantify the value of environmental entities. An example would be ascertaining how much above market prices for timber people are prepared to pay from sustainably managed forest. If in future these values were to be included into cost benefit analyses, very different development alternatives may be produced.

Rainforest may also have increasing commercial value beyond that of the conventional products which it produces. The principle of paying for carbon emission established at the Kyoto conference on climate change and the possibility that rainforest may have economic value as a sink for carbon is causing governments to look again at their plans for deforestation and development (*see* Boreal Forest Carbon Flux and it s Role in the Implementation of the Kyoto Protocol Under a Warming Climate, Volume 4). Similarly, it is now recognized that the biodiversity of rainforest is of value commercially, as a bank of genetic plant and animal material, but also because it is now recognized that all species have an intrinsic existence value. In some countries strict laws are being passed to protect rainforest nations from so-called bio-piracy, the prospecting and export of plant material for commercial exploitation. New awareness by governments of the value of rainforest may change development plans, but it is also essential that the local population be consulted. The pressure to deforest will only be removed when it is more economically attractive for the local population to maintain the forest than to remove it.

DEFORESTATION AND DEVELOPMENT

The populations of tropical countries are growing rapidly and there is a continual need for new land: this creates the pressure to deforest (Jepma, 1995); often this pressure results in official government colonization schemes. Against this is the pressure from conservationists to protect the rainforest in its undisturbed state. Although at first sight it would appear that these objectives are incompatible, increasingly the conservation movement is recognizing that while it is essential to maintain large areas of forest reserves, it is neither practical nor desirable for all of the world s rainforest to be kept as a living museum. Equally, governments and development organizations are now recognizing that simply replacing forest with intensive agriculture is often not a sustainable option. The poor forest soils and the humid tropical climate result either in only short-lived settlements, or in sparsely populated

large ranches, which do little to eliminate poverty. The new thinking is that, rather than replacing forest, agriculture should be incorporated into the forest system and the land managed in an integrated way that protects the tropical environment rather than confronts it. The successful formula is not yet known, and it will no doubt vary from place to place. The challenge for science is to produce the new ideas and solutions. These solutions will need to cross the normal narrow disciplinary boundaries and will certainly need to take account not only of the variability in the physical environment of the tropical rainforest zone, but also differences in culture and human aspirations.

Demographic Change: Indonesian Transmigration

Joan Hardjono
Padjadjaran State University, Bandung, Indonesia

The term transmigration refers to government planned and subsidized resettlement of people from Java's more overcrowded rural areas into less densely populated parts of Indonesia. The program, under which some 3.5 million people were resettled between 1950 and 1990, has been responsible for signi cant expansion of the cultivated area in the major islands of the country other than Java.

Transmigration is essentially an exercise in the utilization of marginal land to reduce population pressure in Java (Table 1). The extent of the environmental impacts of the program is difficult to assess, however, for forest conversion by local small-holders and spontaneous settlers and, particularly, rapid expansion in commercial logging account for much of the environmental transformation that has occurred. For many years the planning of settlements was handicapped by a serious misunderstanding of the physical nature of land resources outside Java and by the assumption that luxuriant natural vegetation was a reflection of fertile soils. Many transmigrant families have been unable to earn an adequate livelihood from agriculture because most of the arable farming systems introduced to provide the economic foundation of settlements have been unsuited to local conditions.

Table 1 Population growth in Java, 1930–2000 (Central Bureau of Statistics, Jakarta)

Year	$\times 10^3$
1930	41 718
1961	62 993
1971	76 102
1980	91 270
1985	99 853
1990	107 574
1995	114 733
2000	123 625[a]

[a] Projection.

The first resettlement schemes, established in southern Sumatra prior to 1940, were based on attempts to introduce irrigated rice growing using the methods developed in Java over many centuries (Pelzer, 1945). While this agricultural system in itself had no negative effects on the environment, the agricultural involution characteristic of intensive rice-growing areas in Java (Geertz, 1963) gradually appeared. At the same time the clearing of land upstream of irrigation infrastructure by loggers, local small-holders and the descendants of the original occupiers of the new irrigation areas, who had been forced by the fragmentation of inherited holdings to seek farm land elsewhere, resulted in the silting up of rivers and canals. This in turn reduced the dry season effectiveness of irrigation networks and led to the economic deterioration of these early settlements.

As conventional irrigation systems are expensive to construct, transmigration policy shifted toward the establishment of tidally irrigated settlements in the coastal swamps of southern and western Kalimantan and eastern Sumatra (Hardjono, 1977). The concept was adopted from the agricultural practices of local cultivators, who had long ago devised a way of using the tidal influence in coastal rivers to lift water on to rice fields and to provide drainage. Very few of these settlements have proved economically viable because planners did not understand that the tidal irrigation system is really a form of shifting cultivation. Local farmers plant coconuts in conjunction with rice and then, as soil fertility declines, make new clearings but return regularly to harvest the coconuts. The traditional system has no adverse effects on the environment since the original vegetation is replaced by perennials. Transmigrants, however, are expected to become sedentary farmers on 2-ha holdings. Given acidic soils derived from peat, they can grow no more than one rice crop a year, nor can they cultivate the secondary food crops like corn that they need for subsistence. The consequence is that much of the land cleared for tidal farming has been abandoned to the growth of weeds and grasses.

By far the greater proportion of government transmigration projects have been based on non-irrigated farming (Hardjono, 1986). The land made available for settlements has for the most part been under poor-grade secondary forest or scrub regrowth and in many instances was already degraded by earlier human activity. Settlements have sometimes been established on logged-over forestry concessions or on land where a shortening in shifting cultivation cycles had led to soil deterioration. In some areas transmigrants have been placed on heavily dissected terrain where erosion is well advanced and in others on land covered in alang-alang grass (*Imperata cylindrica*). Soils have mostly been inherently infertile red yellow podsols, whose shallow upper layers have tended to be destroyed by the use of heavy machinery to prepare settlement sites. Inadequate water resources in many areas have exacerbated these problems. In some places settlers have succeeded in bringing this land under cultivation, thus preventing further degradation. But this has been possible only where subsidized inputs like fertilizers and lime were provided or where project planning included finance for the planting of cash crops like rubber.

The general response of government sponsored transmigrants to the low returns obtained from farming has been to seek seasonal off-farm wage labor or to abandon their holdings completely. The environmental consequences have been two-fold: land degradation has accelerated as neglected fields become covered in alang-alang grass, and encroachment on forested land outside the project area has occurred. In the latter case transmigrants have turned to the felling of trees to produce charcoal commercially, to obtain timber for sale to local sawmills or to make clearings in which to plant cash crops like coffee and pepper in imitation of local small-holders.

Since 1990 government transmigration targets have been considerably reduced because of budgetary constraints and also because of recognition of the fact that arable farming is not an appropriate type of land use (Table 2). Other agricultural patterns have been introduced in the form of privately owned oil-palm plantations and timber estates, which are connected with transmigration only in so far as they depend on transmigrant families from rural Java for their labor force.

In its Indonesian interpretation, transmigration does not include spontaneous migrants who move without government assistance from one part of the country to seek a living in another. Some come from elsewhere in the same province or island while others migrate from Java and Bali. They purchase usage rights to land from local people but, although they adopt the slash and burn techniques of shifting cultivators, they do not plant perennials when fertility declines. As they move on and make new clearings, abandoned fields soon become covered in secondary growth. In the absence of appropriate agrarian legislation, it is difficult to restrict the movement of these settlers, who are responsible for much of the uncontrolled land clearing that has damaged the environment outside logging concessions in recent years.

Table 2 Fully and partly sponsored transmigrant families, 1950–1997 (Department of Transmigration, Jakarta)[a]

Period	No. of families[b]
1950–1954	22 317
1955–1959	32 242
1960–1964	26 456
1965–March 1969	21 633
1969–March 1974	39 511
1974–March 1979	52 084
1979–March 1984	365 977
1984–March 1989	228 422
1989–March 1994	77 485
1994–March 1997	74 565[c]

[a] Figures include local migrants moving within the same province.
[b] Each family has an average of five members.

Demographic Change: Peopling of the Pacific Islands

Patrick D Nunn
The University of the South Pacific, Suva, Fiji

The initial peopling of the Paci c Islands 3500- 800 years ago was a remarkable achievement, one which began tens of generations before any other group of humans developed the

ability to cross such large expanses of open ocean. The linkages between the rst Paci c Islanders and the environments they settled continues to be vigorously debated. Many authors have highlighted the effects of the rst humans on the pristine, vulnerable environments of Paci c Islands, and virtually overlooked the ways in which these environments (and the ways in which they changed) affected human lifestyles. It is now becoming clear that the lifestyles of the rst Paci c Islanders were in uenced considerably by the new environments they encountered, and that subsequent environmental change was the major cause of cultural transformation among many Paci c Island peoples.

OUT OF THE WEST

The first people to colonize the Pacific Islands came from the western Pacific Rim (see Figure 1). The clearest evidence is linguistic; the root of the Austronesian languages, which are the native tongues of most Pacific Islanders, lies in southern China and Taiwan. It is reasonable to suppose that this region was occupied around 10 000 7000 years ago by people practicing fledgling agriculture. During this period, this region was also more extensive because the sea level was lower, the island of Taiwan being connected to the Asian mainland, and the mouths of the Huanghe and Yangtze rivers being far seaward of their present positions (Nunn, 1999).

It may have been sea-level rise and the consequent inundation of many thousands of square kilometers of low-lying arable land that led to the initial exodus of people from this area around 7000 6000 years ago. They took to the oceans and, making their way south through the Philippines archipelago, finally settled the outer islands of Papua New Guinea around 3500 years ago (Kirch, 1997).

There was already a long-established population who spoke the Papuan language (which also include Australian aboriginals) in Papua New Guinea at this time, and it may be that the Austronesian-speaking emigrants could find space to dwell only in the comparatively sparsely-peopled outliers of this vast island group. Although some of the new arrivals remained in Papua New Guinea, others moved on eastward into the Pacific Ocean.

THE LAPITA COLONIZATION

The journeys of the first Pacific Islanders have been tracked precisely by the remains of the distinctively-decorated pots they manufactured. This style of pottery, named *Lapita* after the site in New Caledonia where it was first discovered, occurs from the outer islands of Papua New Guinea through the Solomon Islands, Vanuatu, Fiji, Tonga and Samoa (Kirch, 1997).

Apparently, within a few hundred years around 3000 years ago, Lapita people colonized, for the first time the eastern outer Solomon Islands, Vanuatu, New Caledonia, Fiji, Tonga and Samoa, routinely crossing ocean gaps of several hundred kilometers on vessels loaded with people, pigs, dogs, corms of taro, coconuts and other items intended to recreate their ideal environments on the islands they encountered. This idea of transported landscapes has proved a useful key to understanding many of the similarities in early human lifestyles across tropical Pacific Islands (Kirch, 1997).

It is a remarkable coincidence that the first permanent human settlement of most Pacific Islands occurred only after sea level had begun falling from its postglacial maximum, a time when the cliffed, reefless coasts of these islands would have become replaced by coasts bordered by broad, fertile plains fringed with coral reefs. Indeed it may be that early humans in the voyaging nursery of western Melanesia had paid many visits to island groups a thousand kilometers or more away to the east long before this time but, finding the coasts of those islands unsuitable for permanent colonization, had returned to their home bases in the west to await a time when the coastal environments of those distant islands became more attractive (Nunn, 1994).

INTO THE EAST

The Lapita cultural complex extends no farther east into the Pacific than Tonga and Samoa, perhaps because enough land had been settled to satisfy all the potential colonizers associated with this wave of migration. There seems to have been a pause of perhaps 1000 years in the eastward colonization of the tropical Pacific at this time. Although there is some debate as to when and where eastward colonization resumed, a plausible scenario is that it happened between Samoa and the Marquesas Islands in northeast French Polynesia about 2000 years ago. A conspicuous feature of this phase of Pacific Island colonization is the absence of ceramic use or manufacture, suggesting it may have been accidental rather than deliberate. It is possible that a fishing party out from Samoa was caught in the Equatorial Countercurrent, which is often both stronger and farther south than normal during El Nino events (*see* El Nino and La Nina: Causes and Global Consequences, Volume 1), and swept eastward to a landfall in the Marquesas. From here, the colonization of the rest of French Polynesia and adjacent island groups appears to have been accomplished fairly rapidly. It has been suggested that the clear skies and reliable trade winds associated with the Little Climatic Optimum (c. 1100 700 years ago in the tropical Pacific) facilitated the long-distance voyages from this Polynesian heartland, which saw the first human settlement of Easter Island (Rapanui), the Hawaiian Islands, New Zealand and possibly even Panama in Central America, several generations before European sailors discovered this vast ocean.

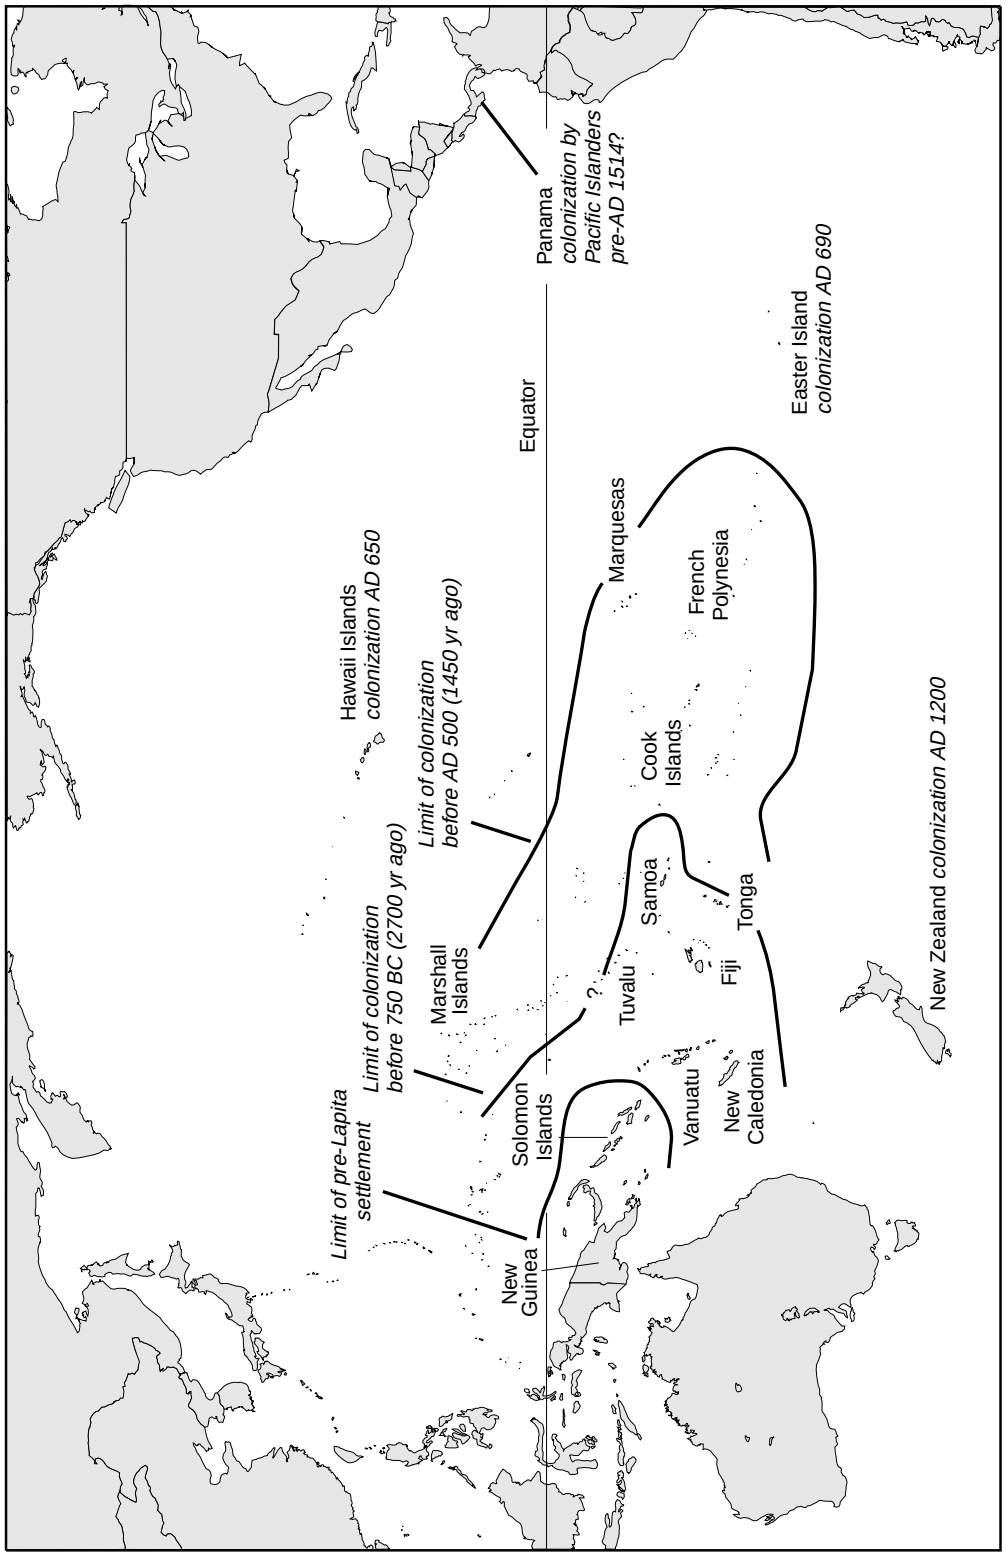

Figure 1 The main Pacific Island groups, showing the chronology of colonization outwards from western Melanesia

EARLY HUMAN–ENVIRONMENT RELATIONS

There is considerable debate about early human environment interactions on Pacific Islands, some authorities claiming that island ecosystems experienced an abrupt and catastrophic change shortly after humans arrived, others inferring that human impact was slower and its effects are obscured by those of non-human environmental changes, particularly those resulting from climate change (Kirch and Hunt, 1997; Nunn 1997, 1999).

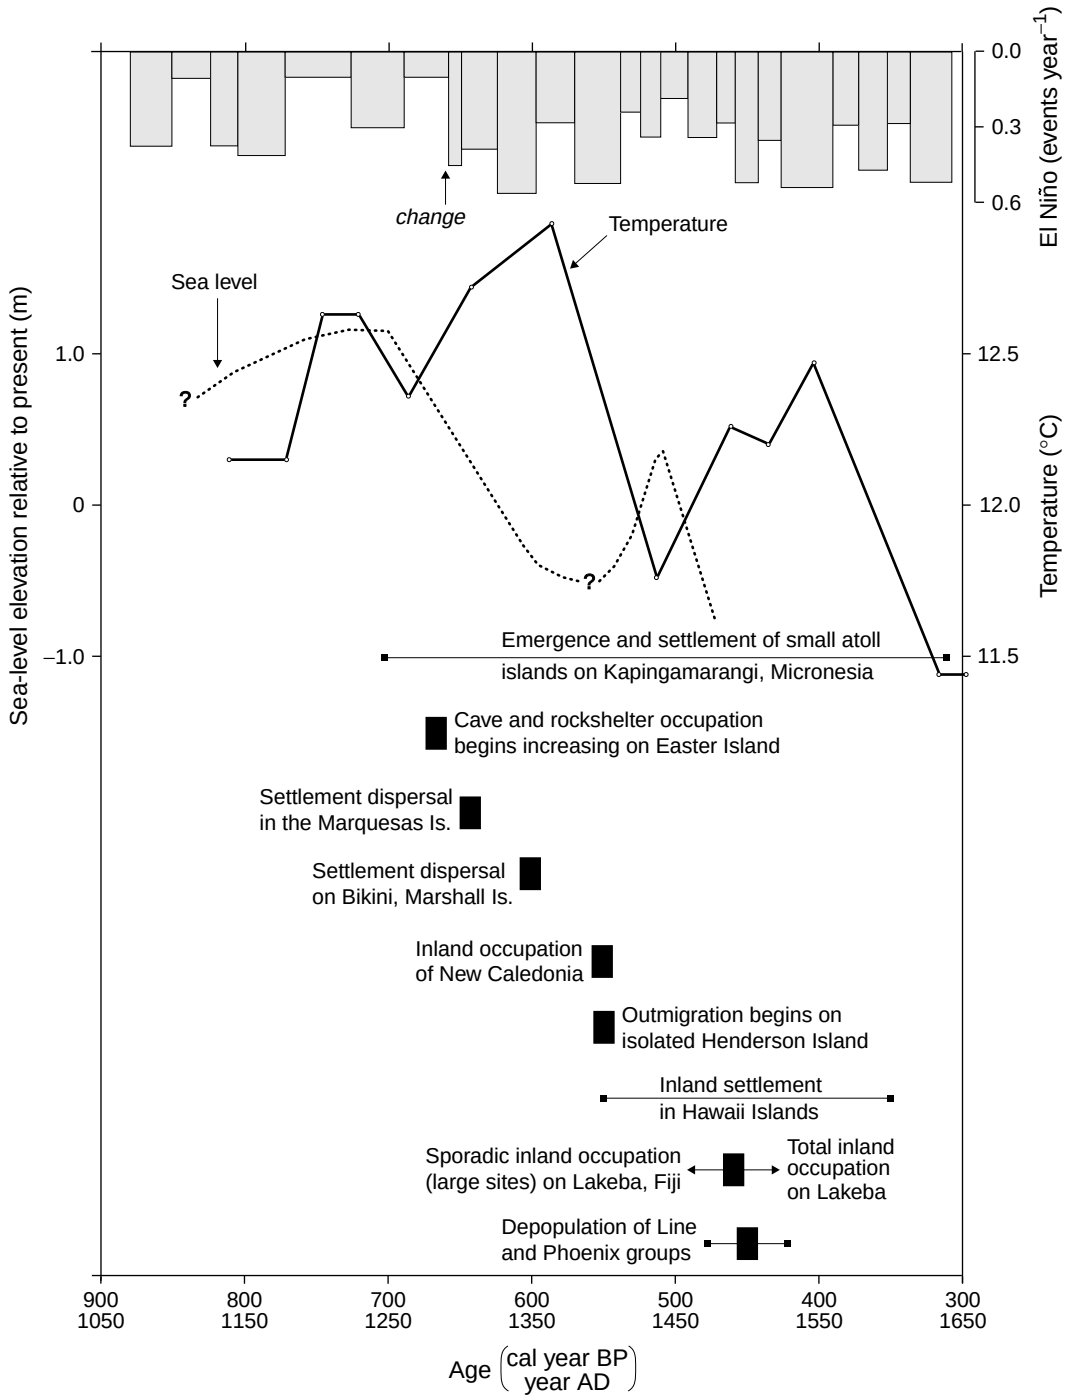

Figure 2 Environmental change and human response manifested by settlement-pattern changes on selected Pacific Islands during the last millennium. All these changes can be interpreted as a consequence of the substantial depletion of the food resource base on many islands associated with the rapid cooling and sea-level fall (and increased precipitation) coincident with the increase in El Niño frequency around AD 1300

It is clear that at the time around 3000 2500 years ago when the Lapita colonization in the southwest Pacific Islands was underway, the climate in the tropical Pacific was becoming cooler and drier, effects that would be expected to have stressed many ecosystems, increasing their vulnerability to rapid change as a result of human arrival. It is possible that much of what has been regarded as a consequence of early human impact is actually (largely) a result of non-human changes, the corollary to which is that, as studies of traditional horticulture in the Pacific Islands suggest, their early inhabitants husbanded rather than recklessly overused the resources available on a newly-discovered island.

The same may not have been true of the central and eastern tropical Pacific Islands on many of which there is evidence that the earliest inhabitants simply moved on to the next uninhabited island once all the birds and bird eggs were gone, as a result of human predation.

Despite the evidence of transported landscapes in different island groups, it is possible to overstress the dominance of human impact at the expense of non-human impacts. This point shows up less well with the low densities of people that settled the Pacific Islands initially but becomes more apparent later.

During the Little Climatic Optimum (1100 700 years ago), for instance, the climate became drier than previously, resulting in the development of water-conservation strategies, primarily agricultural terracing, on many islands. Such strategies required cooperation and, thus, at this time, small isolated settlements were replaced by large nucleated settlements, and the subsequent development of socio-political complexity (Nunn, 2000).

At the end of the Little Climatic Optimum, there was a rapid cooling and sea-level fall, associated with a short-lived rise in precipitation attributable to increased El Nino frequency (Figure 2). This AD 1300 event brought about widespread destruction of the food resource base on many Pacific Islands, resulting in social breakdown that was manifested by the abandonment of large coastal settlements in favor of small, fortified hilltop settlements, and the outbreak of inter-tribal warfare and the associated cannibalism and headhunting, which many writers have supposed to have been endemic to Pacific Island societies (Figure 2). During the subsequent Little Ice Age (600 150 years ago in the tropical Pacific), conditions remained cool but environmental stability resumed and, although people on many islands remained in their hilltop settlements, inter-tribal conflict effectively ended by the time of European settlement around AD 1850 (Nunn, 2000).

Since this time, increased demands on Pacific Island environments have led to many becoming notably less productive, although it remains difficult in many cases to separate human from non-human impacts. The recent warming and increase in tropical cyclone (hurricane) frequency in the South Pacific has caused problems of a magnitude that outweigh deleterious human impacts on many islands (Nunn 1994, 1997).

Demographic Change: the Aging Population

Donald T Rowland

The Australian National University, Canberra, Australia

Population aging is one of the major processes of change in contemporary societies. In the more developed countries, 8% of the population were aged 65 years and over in 1950, compared with 14% in 2000 and a possible gure of 24% in 2050. Less developed countries have lower proportions in the older ages, yet they have the majority of the world's older people. China and India together have greater numbers aged 65 years and over than the whole of Europe, including the former Soviet Union. Textbooks de ne population aging as a rise in the percentages in older ages, but the increase in the numbers of the aged is closely related and important. Even where there are low percentages of older people, families, communities and governments may not have the means to provide adequately for them.

Growth in the numbers of the aged is an unavoidable consequence of falling death rates, while growth in the percentages in older ages is an unavoidable consequence of falling birth rates (fertility). Low mortality and fertility are necessary in a nite world where human welfare is paramount and human numbers cannot expand inde nitely.

Yet world population growth will remain unstoppable until population aging has run its course. Even with low birth rates established, national populations can grow by 50% or more through the expansion of older age groups. Such growth brings with it economic, social and environmental strains requiring major adjustments to an unprecedented situation.

THE PROCESS OF POPULATION AGING

Population aging necessarily accompanies progress towards achieving sustainable development through reducing rates of population growth. All national populations will eventually be old if low birth and death rates become universal. The main phase of growth in the numbers and percentages of older people began in Europe and North America in the 19th century and in Asia, Africa and Latin America from around 1950. Such changes are part of the *demographic transition*, which describes population trends through time and provides a framework for comparing the experience of different countries. The demographic transition identifies progress from a pre-transition stage, with high birth and death rates, to a post-transition stage with low birth and death rates (Table 1). Between them is the demographic transition, during which population growth rises then declines and population aging occurs (Myers, 1990).

Over the demographic transition, national and world age structures evolve from *young*, triangular profiles to *old* rectangular ones. The former indicates high birth rates, the latter low. Figure 1 illustrates these changes, showing the global population in 2000 (young) and the projected situation in 2100 (old). It takes many decades for the declines in birth and death rates to have their full effects on the numbers and percentages in each age group. Thus, growth in the numbers in older ages is typically a delayed result of developments that occurred sixty or more years earlier: the transition in the age structure continues long after completion of the major declines in birth and death rates.

The numbers in older age groups expand throughout the demographic transition because of the long-run effects of lower death rates among the young. The greatest improvements in survival over time occur among infants and children. In the pre-transition stage, up to 50% of infants die before their fifth birthday. Early in the transition falling mortality, due especially to control of infectious diseases and famines, results in more infants and children surviving to maturity and ultimately to the older ages. By the middle of the demographic transition about 80% of children born reach age five and 40% reach age 65 (Table 1). If high birth rates persist, populations remain in the transition

Table 1 Characteristics of populations during and after the demographic transition

	Pre-transition	Mid-transition	Post-transition	Future declining[a]
Crude birth rate[b]	50.0	45.7	12.9	9.8
Crude death rate[c]	50.0	15.7	12.9	14.8
Annual growth rate %	0.0	3.0	0.0	−0.5
Age structure %

stage and stay demographically young; each newborn group or cohort of children will be larger than the one before it. This situation creates substantial population momentum, or growth potential, arising from larger birth cohorts reaching older ages.

As a result of population momentum, the demographic transition brings spectacular growth in the numbers of the aged. For example, in France, the ultimate outcome of the demographic transition will be a doubling of the total population and a 10-fold increase in the numbers aged 65 and over. In India, a five-fold increase in the total will accompany a 40-fold increase in the aged population. In Mexico and Kenya, the numbers of the aged could increase 100-fold and 200-fold, respectively, by the end of the transition (Chesnais, 1990). The highest figures reflect rapid mortality decline in conjunction with delayed fertility decline.

Whereas improvements in survival sustain cohort numbers for longer and increase population momentum, falling birth rates have the opposite effect: they decrease cohort size and reduce momentum. The percentages in older age groups remain low during the demographic transition until birth rates start to decline. Falling birth rates reduce differences between the size of parent and child generations, as families averaging six or more children give way to families averaging two children. Lower fertility causes young triangular age structures to become narrower at the base and more rectangular (Figure 1). The decrease in the representation of children allows the percentages in older ages to increase. The fall in the birth rate is the principal cause of the expansion of the percentages in older ages from less than 3% (pre-transition) to around 20% (post-transition).

REJUVENATION AND EXCESS AGING

Although the demographic transition envisages unidirectional change towards lower birth rates, reversals in the process of aging can happen. One destined to have a substantial impact in the future is the baby boom that occurred after the Second World War in more developed countries, and was particularly protracted in some such as the United States and Australia. The baby boom was a temporary increase in birth rates arising especially from more universal marriage and childbearing. For a time, the baby boom rejuvenated populations, reversing national trends towards population aging. It also created unusually large cohorts, which will reach the older ages in the second and third decades of the 21st century. In the countries most affected, much forward planning of provision for the aged is to prepare for the aging of the baby boom cohorts.

Other exceptions arise because the post-transition stage of the demographic transition is merely hypothetical: it is not the endpoint of population change. The experience of European countries has been to move to a further stage of below-replacement fertility (van de Kaa, 1997). This produces natural decrease (an excess of deaths over births) and hyper-aging with excess proportions in older ages: the age structures become narrower at the base than in the middle. Examples in the early 21st century could include Italy, Spain, Germany and Japan. Since successive cohorts are smaller than those that went before, such populations develop negative momentum, whereby numbers decrease as smaller cohorts reach older ages (Rowland, 1996). Maintenance of such a situation would ultimately bring extinction. Only a rise in the birth rate could reverse this extreme form of aging, illustrated in Table 1 under the heading future declining population.

International migration is sometimes seen as a means of averting decline and rejuvenating populations, but it is seldom an appropriate response to population aging *per se*. The most rapidly aging national populations are so large that huge and socially disruptive numbers of immigrants would be required to make an appreciable difference to the percentages 65 and over. Also, in the long run, the aging of the immigrants themselves would augment the total numbers in the older ages.

REGIONAL VARIATIONS

Future numbers and percentages in the older ages are necessarily uncertain, but World Bank (1994) projections illustrate possible developments. In the year 2000, about 7% of the world s population of 6.1 billion were aged 65 or more (Table 2). This percentage might double by 2050 (world population 9.6 billion) and treble by 2100 (world population 11.0 billion). During the 21st century,

Table 2 Population aged 65 and over, World Regions, 1990–2100

	1990	2000	2050	2100
Numbers 65+ (millions)				
World	330	419	1,435	2406
More developed regions	147	176	324	335
Less developed regions	182	244	1111	2074

the age structures of different regions of the world will probably converge toward the demographically old profile expected at the end of the demographic transition. The more developed regions of the world would still have the oldest age structures, but the contrast with the less developed regions would be smaller than in 2000. Due to sustained high birth rates, Africa may be the last major region to complete the transition, with still only 7% of its total 65 plus in 2050. Europe s figure of nearly 25% 65 and over in 2050 reflects the outcome of below-replacement fertility in many countries, as assumed in the projections, leading to negative momentum and population decline. Italy and Japan, with projected figures of around 30% aged 65 and over in 2050 exemplify hyper-aging. Sweden, had the world s oldest national population in the early 1990s; 18% 65 and over (Kinsella and Taeuber, 1993) but it may reach only 22% aged in 2050, provided that its birth rate remains near replacement level (World Bank, 1994).

The World Bank s projections of the total numbers aged 65 and over show the world s total aged population more than trebling between 2000 and 2050, reaching 1.4 billion in the latter year and 2.4 billion in 2100. In 1990, the aged in the demographically younger less developed regions already outnumbered those in the more developed regions. By 2050, 77% of the world s aged may be in the currently less developed regions, rising to 86% in 2100 (Table 2). The demographic giants of China and India, each with total populations of more than a billion, dominate the global picture. By 2050, China and India could *each* have far more old people than Europe and the United States combined. In India, the population aged 65 and over numbered 11 million in 1950 (3.3% of the total population), around 52 million in 2000 (5.2%) and could reach 237 million in 2050 (14.6%).

CONSEQUENCES

Population aging has implications for resource use and environmental change mainly because of its role in overall population growth and the transformation of national age structures. The effects of these demographic developments are mediated through other factors, such as technology, material living standards and international trade. Thus, similar demographic changes can have different environmental consequences, depending on the nature of the society.

Aging of the Labor Force

Shifts in the age structure can affect the productivity of populations through changes in dependency levels and the aging of the labor force, which everywhere are concomitants of overall population aging. A dilemma for less developed countries is whether to maintain the labor force participation of older workers in the modern sectors of the economy to the disadvantage of the young, better educated and potentially more productive; or whether to foster early retirement and prolong the time lived as a potential tax burden. The productivity of workers, however, is far less a function of age than of skills and health status. The principal distinction is between the aged with high functional capacity and those with disabilities. Experience and

lower rates of absenteeism can reinforce productivity in an older labor force. The aged who are not in the mainstream labor force further constitute a valuable resource for society in helping relatives and engaging in voluntary work. The Chinese government has been particularly active in capitalizing on the aged s status, expertise, and free time, including using *granny police* to monitor use of family planning and adherence to the country s one-child policy (Treas and Logue, 1986).

In more developed countries, voluntary and involuntary early retirement are restraining the aging of the labor force. During the 20th century, retirement became established as a stage of later life, as well as one commencing at younger ages. In the United States in 1890, 89% of males aged 55 64 were in the labor force, compared with 68% at ages 65 and over (Davis and van den Oever, 1981). By 1990, these figures had fallen to 68 and 16%, respectively, but changed relatively little in subsequent years to 1997 (US Bureau of the Census, 1998). Early retirement entails not only a shortening of labor force participation, but usually also a prolonging of reliance on publicly funded pensions. In the future, males may spend more than half their lives outside the labor force. The higher participation of women in the labor force has offset much of the lower participation of men (Davis and van den Oever, 1981).

Dependency

The costs associated with providing for the health and welfare needs of larger numbers of the aged raise pressures on governments to increase economic growth, which may heighten conflicts with environmental goals. At the same time, a rising proportion of voters will be above middle age, reinforcing imperatives for policies and programs supportive of the needs of older people. Thus, population aging has implications for the environment through the need to give priority to supporting greater numbers at extra *per capita* costs to the State, in a time requiring critical decisions concerning sustainable use of resources and the environment.

Yet currently, in less developed countries with scarce resources, aging is seldom regarded as a high priority amid the many other demands of social and economic development (Rowland, 1994). There is a strong expectation that the family will provide for older relatives, but this is becoming less tenable in the face of the rising labor force participation of women and the separation of relatives through inter-regional migration (Myers, 1995). In the past, only a small proportion of families had surviving grandparents, which meant that traditional family support for the frail aged was called upon less frequently. Today, the pace of aging in less developed countries is well ahead of institutional preparedness to meet health and social welfare needs (Treas and Logue, 1986).

Demographic dependency ratios compare the numbers of children and older people with the numbers in the working ages. Such ratios are only crude indicators of economic demands, since they take no account that some in the working ages are not economically active while others in the so called dependent ages may be independent in economic terms as well as in other ways. Statistics in Table 1 show that child dependency and total dependency peak in the middle of the demographic transition, at which time there may be around 90 dependants, mainly children, per hundred people in the working ages, 15 64 years. By the end of the transition, total dependency actually falls to around 60 workers per hundred dependants, of whom half are under 15 and half are 65 or more. Thus old, post-transition populations have relatively low levels of dependency. Table 1 shows that a future declining population, exemplified by the World Bank (World Bank, 1994) projection for Italy in 2050, could again have an overall dependency level of 90, two-thirds of whom would be 65 plus. A key question therefore concerns the relative cost of supporting children compared with older people.

Per capita public expenditure on older dependants in more developed countries is said to be two or three times higher than on children. Nevertheless, other estimates suggest that a child absorbs more resources than an old person, with the result that the first 20 years of life cost more than the total years lived after 60. Thus, combining public and private expenditures, children appear more expensive *per capita*. This implies that the decreased cost of supporting children is offsetting the increased cost of supporting the aged. Much of the decreased cost of children, however, will be a saving in private expenditure, which the taxation system cannot easily redirect to the aged (Easterlin, 1996).

Technology and rising standards of education may facilitate adjustments to population aging in more developed countries, as they have to other demographic changes in the past (Easterlin, 1996). Yet continuing economic growth is also likely to be a prerequisite for meeting the needs of greater numbers of older people without compromising living standards and standards of care. Additional responses will be targeting government expenditure on the most needy and encouraging greater self-provision in later life. Such responses are evident in the strategy for aging populations that the Organisation for Economic Co-operation and Development (OECD) (OECD, 1999) has formulated, elements of which are:

- removing financial incentives for early retirement;
- improving job opportunities for older workers, including part time employment;
- reducing public pension benefits and developing advance funded pensions systems;
- achieving a greater focus on cost effectiveness in health and long-term care.

FUTURE ALTERNATIVES

Aging populations have three possible futures: (1) rejuvenation through higher fertility, which would start a new phase of population growth; (2) stabilization of the age structure and population numbers, with growth rates averaging zero; (3) hyper-aging, or super-aging (Myers, 1998) through maintenance of below replacement fertility, leading to excess proportions in the older ages, negative momentum and population decline. In the 21st century, there is likely to be continuing diversity in national population trends, with all three scenarios represented in different places at different times. Yet the second scenario is the only viable long-term global future. Just as the world s population has almost certainly had a young age structure throughout its history (Coale, 1972), the global population will have an old age structure in the future: there is no other age structure consistent with low fertility and low mortality. Nevertheless, a demographically old global population is not a possibility until late in the 21st century, since many less developed countries are still in the midst of the phase of high growth and age structure transformation.

Desertification, Definition of

Desertification has been defined by the United Nations (UN) as land degradation in arid, semi-arid and dry sub-humid areas resulting from various factors, including climatic variations and human activities (UNCED, 1992).

REFERENCE

UNCED (1992) *Earth Summit Agenda 21, Program of Action for Sustainable Development*, UNEP, New York.

MARTIN WILLIAMS *Australia*

Desertification

Martin Williams

Adelaide University, Adelaide, South Australia

Deserti cation is currently de ned as land degradation in arid, semi-arid and dry sub-humid areas resulting from various factors, including climatic variations and human activities. This de nition was put forward, debated and accepted at the United Nations Conference on Environment and Development (UNCED) held in Rio de Janeiro

in June 1992, colloquially known as the Earth Summit (UNCED, 1992). The UNCED de nition superseded an earlier one used by the United Nations Environment Programme (UNEP) in which deserti cation was de ned as land degradation in arid, semi-arid and dry sub-humid areas resulting mainly from adverse human impact (UNEP, 1992a). The signi cance of the 1992 UNCED de nition is that it allows a speci c role for climatic variations. In contrast, earlier de nitions were almost exclusively focused on human mismanagement and ignored the pervasive in uence of climate.

WHAT IS DESERTIFICATION?

The 1968 1974 drought in the Sahel region of West Africa rekindled international interest in land degradation in Africa and demonstrated very starkly some of the ways in which climatic desiccation and prolonged droughts can contribute to dryland degradation. French hydrologists and meteorologists drew attention to the severity of this drought at the International Geophysical Conference in Grenoble in August 1975. International concern over land degradation and water shortage was the catalyst for the United Nations (UN) to host a Water Conference in Argentina in March 1977, and for UNEP (United Nations Environment Programme) to host the UN Conference to Combat Desertification, Nairobi, August 1977.

At this conference a number of definitions were debated. One proposed that the term desertization be used in a very restricted sense to denote the extension of typical desert landscapes into semi-arid regions with 50 300 mm of rain a year. This definition specifically excluded wetter areas. An opposing view, ultimately accepted and endorsed by UNEP, was that areas of higher rainfall should be included. One outcome of the 1977 Nairobi conference was the definition of desertization as the spread of desert-like conditions in arid or semi-arid areas up to 600 mm, due to human influence or climatic change (Glantz, 1977). Later definitions tended to ignore the climatic factor and even to suggest that drought was a human construct arising from destructive forms of land use. As time progressed, the UNEP definition stressing adverse human impact was widely adopted and was used in the first (1992) but not the second (1997) edition of the *UNEP World Atlas of Deserti cation.*

Political and scientific awareness of desertification was enhanced by the publication of the two editions of the *UNEP World Atlas of Deserti cation* (UNEP, 1992a, 1997). In the comparatively short time between the publication of the first and second editions of this very useful atlas, there was already a much clearer scientific appreciation of the nature and causes of climatic variations, including global floods and droughts. This is very clearly reflected in the editorial discussion of climatic fluctuations in the second edition (UNEP, 1997).

The original roots of the term *deserti cation* connote abandoned or forsaken, and come from *desertum*, the neuter past participle of the Latin verb *deserere*. The present definition refers to land degradation and its possible causes. One consequence of such land degradation is that the land can no longer sustain much in the way of human settlement and so becomes abandoned. In that sense, the present definition is not too far removed from the original Latin meaning.

EXTENT AND SEVERITY OF DESERTIFICATION

It is not easy to measure the extent and severity of desertification. The earlier estimates of desertification put forward by UNEP in 1977, 1984 and 1987 (UNEP, 1992b) have been criticized as exaggerated and unreliable. Some of the estimates were based on questionnaires sent out to government officials in countries often already in the throes of severe drought and widespread social distress and famine. This naturally colored their perceptions of the magnitude of the problem (Thomas and Middleton, 1994). Granting that earlier reports were often overestimates, later estimates did suggest that desertification was a major global scourge. The revised estimates of Dregne *et al.* (1991) indicated that roughly three-quarters of all rangelands on each of the six continents were to some degree degraded. From 15 30% of the land in irrigated areas was degraded. Over half of the rain-fed croplands in Africa, Asia and Europe were considered degraded, over one-third in Australia and South America, and almost one-fifth in North America.

Criticism of the poor quality of the data and its lack of credibility persisted, and prompted UNEP to seek improved and less subjective ways of monitoring desertification.

UNEP therefore approached the International Soil Reference Center (ISRIC) in Holland and in 1987 UNEP and ISRIC began the Global Assessment of Soil Degradation (GLASOD) project. The GLASOD data were used very effectively in both editions of the *World Atlas of Deserti cation* (UNEP, 1992a, 1997). Table 1 is based on the latest published estimates for the global extent and severity of desertification (UNEP, 1997). The lack of adequate ground control remains a fundamental weakness even now, so that these estimates should be considered as provisional, order-of-magnitude values. Irrespective of the less than ideal quality of the data, one conclusion is all too clearly evident. Desertification is a major problem on every inhabited continent. This applies both to the relative proportions of land affected and to the total areas of land degraded.

Table 1 Extent of soil degradation in susceptible drylands, grouped by continent, in millions of hectares[a]

	Type of soil degradation				
Region	Water erosion	Wind erosion	Chemical deterioration	Physical deterioration	Total
Africa	119.1	159.9	26.5	13.9	319.4
Asia	157.5	153.2	50.2	9.6	370.5
Australasia	69.6	16.0	0.6	1.2	87.4
Europe	48.1	38.6	4.1	8.6	99.4
N America	38.4	37.8	2.2	1.0	79.4
S America	34.7	26.9	17.0	0.4	79.0
Total	467.4	432.4	100.7	34.7	1035.2

CAUSES AND CONSEQUENCES OF DESERTIFICATION

Part of the reason for the difficulty in defining desertification stems from the very real problem of how to distinguish human impact from the long- and short-term impact of natural climatic variability in arid and semi-arid areas (Hare and Ogallo, 1993). Detection of cause and effect may require careful and sustained interdisciplinary research and long-term monitoring. For example, 17 years of satellite monitoring of vegetation cover along the southern margins of the Sahara revealed considerable variation from year to year in response to yearly variations in rainfall (Tucker and Nicholson, 1999). One conclusion from an earlier study by Tucker *et al.* (1991) extending from 1980 1990 was that at least 10 years of observations were needed to detect any possible trends in the vegetation cover in this region. A similar conclusion almost certainly applies to other dry regions of the world where the annual rainfall is highly variable and the response of annual and ephemeral plants equally so. It is easy to reach wrong conclusions based on too few observations, particularly if the comparison is between the state of the landscape towards the end of a series of wet years and the situation a decade or two later during the height of a prolonged drought.

A good example of this danger comes from the observations of Lamprey (1975) in Northern Darfur and Kordofan Provinces of Western Sudan. Lamprey s team used vehicles and aerial observations to map the boundary between full desert and desert scrub or grassland. They then compared the position of their mapped desert boundary with that defined by Harrison and Jackson after their 1958 survey of the vegetation of the Sudan (Harrison and Jackson, 1958a,b). Comparison of the two boundaries showed that the southern margin of the desert in 1975 was 90 100 km farther south than it was in 1958. This apparent southward shift of the desert margin by 100 km in 17 years, when averaged, gives a mean rate of advance of 5.5 km per year. Such a conclusion is highly misleading and seems to imply that the Sahara is advancing relentlessly at a steady southward rate of 5 6 km year^{-1}. Overgrazing may have caused the change in vegetation mapped by Lamprey in 1975, but it could equally have been a result of the severe drought that began in 1968 and persisted intermittently over the next 15 years. Alternatively, and more plausibly, the loss of plant cover may have been caused by a combination of drought and human impact. This example highlights the difficulty in distinguishing clearly between land degradation triggered by anthropogenic acceleration of natural processes and changes in plant cover arising from sustained rainfall deficit.

Although drought is neither a sufficient nor a necessary cause of desertification, the combination of drought and inappropriate forms of land use such as overgrazing, overcropping, and irrigation with inadequate drainage will all precipitate land degradation. Mabbutt (1978) recognized this when he defined desertification as a change to a more desertic condition, and pointed out that it involved impoverishment of ecosystems, accelerated soil degradation, reduced plant and animal productivity, and impoverishment of dependent human livelihood systems. When there was a combination of climatic stress and land-use pressure, the almost inevitable result was land degradation (Mabbutt, 1978).

Williams and Balling (1996) have recently reviewed the worldwide evidence for desertification. Some of the more obvious signs of dryland degradation include accelerated soil erosion by wind and water; salt accumulation in the surface horizons of dryland soils; a decline in soil structural stability with an attendant increase in surface crusting and surface runoff and a concomitant reduction in soil infiltration capacity and soil moisture storage; replacement of forest or woodland by secondary savanna grassland or scrub; an increase in the flow variability of dryland rivers and streams; an increase in the salt content of previously freshwater lakes, wetlands and rivers; and a reduction in species diversity and plant biomass in dryland ecosystems (Williams and Balling, 1996). Table 2 adds further detail

Table 2 Some causes and consequences of desertification[a]

Trigger factor	Consequences
Direct land use	*Physical processes affected*
Over-cultivation (decreased fallows, mechanized farming)	Decline in soil structure, soil permeability, depletion of soil nutrients and organic matter, increased susceptibility to erosion, soil compaction, dune mobilization
Overgrazing	Loss of biodiversity and biomass, increased soil erosion by wind and water, soil compaction from trampling, increased runoff, dune mobilization
Mismanagement of irrigated lands	Causes waterlogging and salinization of soils, hence lower crop yields, possible sedimentation of water reservoirs
Deforestation (burning, fuel and fodder collection)	Promotes artificial establishment of savanna vegetation, loss of soil-stabilizing vegetation, soil exposed and eroded, soil desiccation, increased frequency of dust storms, dune mobilization
Exclusion of fire	Promotes growth of unpalatable woody shrubs at the expense of herbage
Indirect government policies	Drives over-exploitative land-use practices
Failed population planning policies	Increases need for food cultivation, hence over-exploitation
Irrigation subsidies	Exacerbates flooding and salinization
Settlement policies/land tenure	Forces settlement of nomads, promotes intensive use of land which often exceeds carrying capacity
Improved infrastructure (roads, large dams, canals, boreholes)	Although beneficial, can exacerbate the problem by attracting increased livestock and human populations or increasing risk from salinization, possible lowering of ground-water table below dams, silting up of reservoirs, waterlogging; promotes large-scale commercial activity with little local benefit, flooding may displace people and perpetuate cycles of poverty
Promotion of cash crops and a push towards national/international markets	Displaces subsistence cropping, pushes local people into marginal areas to survive, promotes less resilient monocultures, and promotes expansion and intensification of land use
Price increases on agricultural produce	Incentive to crop on marginal land
War	Valuable resources, both human and financial, are expended on war at the expense of environmental management and the needs of the people; large-scale migration with resultant increased pressure on receiving areas
High interest rates	Forcing grazing or cultivation to levels beyond capacity
Natural	
Extreme drought	Decreased vegetation cover and increased land vulnerability to soil erosion. Creates an environment which exacerbates over-exploitation
Ecological fragility	Impact of land-use practices – impact also depends on resilience of environment

and lists some of the more important causes and associated consequences of desertification.

OVERGRAZING, DROUGHT AND DESERTIFICATION

The Sahel drought that began in West Africa in 1968 and extended along the southern margins of the Sahara to Ethiopia and Somalia drew world attention to the impact of severe drought on desertification processes (Glantz, 1987; Grainger, 1990; Mainguet, 1994). (*Sahel* is Arabic for border or shore and broadly refers to the southern margin of the Sahara in the region between Mauretania and Chad). The Sahel drought afflicted over 500 million people in over 15 African nations, and resulted in widespread crop failure, livestock deaths, famine, and large-scale migration of environmental refugees out of their traditional grazing

lands and villages to urban fringe dwellings and refugee camps.

The severity of the Sahel drought prompted some scientists to ask whether a reduction in plant cover caused by overgrazing may have led to a decline in regional rainfall. During the 1970s, several workers analyzed the possible links between overgrazing and albedo change as a possible cause of prolonged drought in the Sinai desert and the Sahel. Charney *et al.* (1975) suggested that overgrazing in the Sahel reduces the surface plant cover and hence increases the albedo. (Albedo is the proportion of incoming solar radiation reflected from the earth s surface). The increase in albedo would result in lower land surface temperatures during the day and hence in a reduction in local convection, resulting in less rainfall (Figure 1). An obvious way to test these ideas is to measure albedo and temperature over areas of varying plant cover. Albedo measurements from satellites have yielded contradictory data. Surface measurements of albedo in Niger show significant seasonal variation in albedo and a far more limited range between vegetated and non-vegetated surfaces than proposed by Charney and his colleagues.

Perhaps the greatest single weakness of the albedo drought model lies in its failure to explain the globally synchronous pattern of historic floods and droughts over the last few centuries (Ropelewski and Halpert, 1987; Diaz and Markgraf, 1992). The 1980s and 1990s witnessed a resurgence in studies of the links between ocean surface temperature, atmospheric pressure and the global distribution of severe floods and droughts. The pioneering work of Sir Gilbert Walker in the 1920s was rediscovered and extended. In particular, a growing number of studies considered the role of El Nino/Southern Oscillation (ENSO) events and regional anomalies in sea surface temperature in controlling the incidence of major floods and droughts in widely scattered parts of the world (*see* El Nino/Southern Oscillation (ENSO), Volume 1; Southern Oscillation, Volume 1). For example, the Southern Oscillation Index (SOI), defined by Walker in 1924, is a useful tool in predicting year-to-year variations in the flow of the Blue and Main Nile. (The SOI is a measure of the atmospheric pressure difference between Darwin and Tahiti.) Time series analysis shows that there is a statistically significant correlation between years of low Nile flow, drought in Indonesia (shown also by years of narrow tree rings in the teak tree *Tectona grandis*), and years of summer monsoon failure in India and Eastern China (Williams and Balling, 1996). The opposite is also true, with years of extreme flooding occurring synchronously in all of these regions. The example of Indonesia shows that the influence of ENSO events extends well beyond the present drylands. Severe fires devastated parts of the tropical rainforests of Indonesia and Brazil during the 1982 1983 and 1997 1998 ENSO-related droughts, highlighting the importance of fire as an agent of desertification.

Although overgrazing is not responsible for the prolonged nature of the Sahel drought, drought itself can lead to local overgrazing, which can in turn accelerate soil erosion by wind (Figures 2 4) and water, and can precipitate the mobilization of previously vegetated and stable dunes. The eastern borders of the Great Indian Desert of Rajasthan, the southern margins of the Sahara from the Atlantic to the Nile, and the eastern and southern marches of the Gobi desert are all covered in sand dunes that have remained vegetated and relatively stable for the last 10 000 or so years. The shrubs and grasses that have long colonized the surface of these sand dunes act as highly efficient dust traps. The clay- and silt-size desert dust is washed down through the

surface of the dune to form bands of silty clay that parallel the original aeolian bedding planes of the dunes. These clay bands, together with plant roots, give extra mechanical strength to the dune and contribute to its immobilization. The fixed dunes of Africa and Asia are attractive to cultivators and pastoralists alike. The soils are easy to till and crops grow rapidly during the summer rains when photosynthesis is at a maximum. The trees, shrubs and grasses growing on the dunes provide reliable grazing for sheep, goats, cattle and camels. This happy state of affairs can become severely disrupted during times of severe drought combined with over-stocking.

Northern China offers some salutary lessons in this regard. For over 50 years, desertification has been a matter of great concern in Northern China (Ci, 1998; Williams, 2000). The Alashan area in the north-west of Inner Mongolia is the focus of much current attention because of an accelerating influx of sand into the Yellow River from remobilized desert dunes. For example, the dunes along an 80 km reach of the Yellow River left bank opposite the industrial city of Wuhai are currently advancing from the north-west at rates of up to $10\,m\,a^{-1}$. An estimated 80 million m^3 of sand is being blown into the river each year in this sector.

Alashan is one of the driest regions in China and covers an area of about 270 000 km^2. Rainfall declines from about 300 mm in the east to less than 50 mm in the west. Fixed and semi-active dune-fields cover about 90 000 km^2 and are the areas most vulnerable to desertification. Until the 1950s many of these low dunefields and sandsheets were covered in a relatively dense cover of shrubs, trees and grasses. Since that time the human population has doubled and livestock numbers have tripled. Greatly increased stock numbers, the large influx of immigrants from the south, and the occurrence of sporadic but severe droughts over large tracts of Alashan have resulted in widespread and locally severe desertification and associated ecological deterioration. Official local estimates suggest that some 30 000 km^2 of land are now severely degraded and that the rate of desertification is increasing by about 1000 km^2 each year. Monitored rates of dune advance range from more than $10\,m\,a^{-1}$ near the Yellow River to less than $1\,m\,a^{-1}$ farther inland (Williams, 2000). Control of desertification along the Yellow River is now an important element of China s national plans to combat desertification (China s Agenda 21, 1994). Control measures to arrest dune movement include tree-planting and extensive use of the straw mulch checkerboard technique, especially along the main railway line linking Lanzhou to Baotou.

DEFORESTATION, BIOMASS BURNING AND DESERTIFICATION

The importance of fire as an agent of desertification has been noted earlier. Humans have long been makers and users of fire. Archaeological evidence suggests that our ancestors began to use fire well over one million years ago. The Neolithic inception of early plant and animal domestication in widely scattered parts of the globe some 5 10 000 years ago led to clearing of forest and woodland for cultivation. The process accelerated as urban centers developed, with trading empires needing navies of wooden ships, culminating in the enormous demands for timber triggered by the industrial revolution. The tropical forests and savanna woodlands did not escape the impact of axe and fire. The scholarly French forester Aubréville (1949) has documented in great detail the replacement of tropical

African rainforest by secondary savanna and scrub as a result of tree clearing and burning associated with shifting cultivation and used the term *deserti cation* to encapsulate this process. Decreasing fallow cycles prevented tree regeneration and induced a vicious spiral of ever more xeric vegetation. One of his main conclusions was that human-induced deserts are forming today in Africa in areas receiving 750 1500 mm of rain a year.

Another aspect of the regular burning of savanna woodlands (Andreae, 1993) and of the accelerating burning of tropical forests that needs to be emphasized, is the question of feedback processes (Schlesinger *et al.*, 1990). Just as droughts and strong winds may increase the risk of fire, so too can more frequent and more widespread fires have an influence on local and regional climate. The amount of soot emissions (5.7 Tg C year^{-1}) (1 Teragram (Tg) is 1×10^{12} g) and fine particulate emissions (25.0 79.0 Tg year^{-1}) from biomass burning are almost identical to those from fossil fuel combustion (Ghan and Penner, 1992). Carbon released each year from shifting cultivation amounts to 500 1000 Tg C year^{-1}, while permanent deforestation, savanna fires, firewood burning, and burning agricultural wastes release a further 200 700, 300 600, 300 600 and 500 800 Tg C year^{-1}, respectively (Crutzen and Andreae, 1990). About 60% of the humid savannas are burned each year with an estimated fire efficiency of 83%, compared to only 0.6% of tropical forests at a fire efficiency level of 30 40% (Cachier, 1992). These estimates would need to be revised upwards for tropical forests given the greatly increased rates of burning in Brazil, Colombia and Indonesia since 1992.

Extensive tree clearing and burning is not of course restricted to the lowland forests and savannas of Africa, Asia and South and Central America; when conducted in mountainous areas, the downstream effects can also be severe. Removal of forest in tropical uplands can alter the local hydrological balance through increased runoff and reduced infiltration. Accelerated loss of soil from highland catchments can lead to siltation in reservoirs far downstream and not always within the same country. For example, accelerated soil loss from the Ethiopian uplands has led to siltation in several of the major tributaries of the Nile within the Sudan. By 1996, the capacity of the Roseires reservoir on the Blue Nile had been reduced by almost 60% through silt accumulation and that at Khashm el Girba on the Atbara, by 40%.

Hurni (1999) has painted a graphic picture of accelerated soil erosion in some parts of the Ethiopian uplands. In one region in Gojjam Province, the area cultivated rose from 40% in 1957 to 77% in 1995, while natural forestland decreased from 27% to 0.3%. Traditional farming methods recognized that soil losses during cultivation were high and so allowed long years of fallow for the soils to recuperate. The increasing demand for land has meant a reduction in fallow to virtually zero and an expansion of the area under cultivation. According to Hurni, annual rates of soil loss amount to about 40 tonnes ha^{-1} (2 mm a^{-1}) on mountain slopes, but attain rates of over 300 tonnes ha^{-1} (15 mm a^{-1}) during cultivation years, or some 5 10 times more than in non-mountainous areas (Hurni, 1999). These rates are far in excess of the long-term geological rates of erosion documented for this region, which amount to 0.01 mm a^{-1} in the Ethiopian headwaters of the Blue Nile. Of great concern is the progressive increase in soil erosion in the highlands of Ethiopia over the past 100 years. The rate of erosion in the Blue Nile headwaters during the 70 years before completion of the Aswan High Dam was 0.12 0.24 mm a^{-1}. In the 1970s annual soil loss from parts of the Ethiopian plateau was roughly 0.4 1.0 mm a^{-1}, and in the 1990s it was nearly double that rate.

IRRIGATION, DRYLAND SALINITY AND DESERTIFICATION

Salinity has always posed a problem to farmers in semi-arid areas. Rain contains a small amount of marine salt (cyclic salt). In humid areas salt is leached out of the soil and returns to the ocean in rivers. In drier areas leaching is less effective and so various salts tend to build up in the soil profile or at greater depths in the underlying sediments and groundwater. The more soluble sodium chlorides (NaCl) are more readily dissolved and re-precipitated than the less soluble carbonates and sulphates such as calcium carbonate ($CaCO_3$) and gypsum ($CaSO_4 2H_2O$). Since these processes have been operating intermittently over millions of years, the more arid regions of the world where evaporation greatly exceeds rainfall have an abundance of carbonate, gypsum and rock salt or halite. These areas are naturally saline and are not a result of human-induced desertification. Our concern here is with salinity resulting from human actions, especially through irrigation and clearing of native vegetation.

Large-scale irrigation projects in many parts of the arid world have failed to achieve their full potential through inadequate attention to soil drainage, canal maintenance, and the belated discovery of concentrated pockets of highly saline subsoil and groundwater within the irrigated areas. Seepage from irrigation canals can cause waterlogging and accumulation of progressively more salt in shallow closed depressions, which operate as natural evaporating basins (*see* Waterlogging, Volume 3). If the soils beneath these depressions are even slightly permeable, surface salts may be transferred in solution to shallow groundwater aquifers, and hitherto fresh water may become brackish or saline.

Salt accumulation in the irrigated Indus basin in the 1960s prompted a massive remedial effort to lower rising

water tables using tube wells to pump out excess water. In the 1980s efforts to halt dune encroachment in Northern China through irrigated shelter belts of trees poorly adapted to aridity led to salinization through over-irrigation and evaporative concentration of salt in the irrigation water. The Gezira irrigation scheme in Central Sudan provides up to two-thirds of the export revenue of the Sudan from long-staple cotton grown on less than 1% of the total land area. This project is one of the more successful big irrigation projects in the world and there has been minimal salt build-up in the soils except in a few local areas near the White Nile. At least five factors have contributed to this success: skilful local farmers, efficient management of canals, appropriate irrigation schedules, adequate drainage outlets, and very low salt concentrations in Blue Nile irrigation water.

We saw earlier that in dry areas, salt accumulation in soils stems from inadequate leaching by percolating rainwater. The reverse is true of the southern third of Australia, where European settlers cleared extensive areas of native vegetation for pasture and crops. Half the original woodland and forest that grew 200 years ago has now gone from Australia. The settlers were unaware of the role played by deep-rooted eucalypt trees as natural groundwater pumps. (Groundwater recharge under native vegetation is 1 2 mm $year^{-1}$; under wheat cultivation it is 40 120 mm tr^{-1}). The result was a slow but inexorable rise of local and regional groundwater levels, bringing dissolved salts to the surface and killing all plants not adapted to salinity (*see* Salinity and Agriculture, Volume 3).

This process of dryland salinity has resulted in huge loss of productive agricultural land in Southern Australia. In Western Australia, the area of saline land was 1.6 million ha in 1994 or about one-tenth of the cleared agricultural land in that state. In 1992 over 200 000 ha of the Murray Darling basin were in the grip of dryland salinity. Corresponding figures for South Australia and Victoria were, respectively, over 400 000 and 150 000 ha (Commonwealth of Australia, 1996). The losses in terms of agricultural production amount to over Aus.$500 million $year^{-1}$, so that considerable effort is now being devoted to arresting the process and preventing further damage.

In October 1999, the Murray Darling Basin Ministerial Committee published its salinity audit of the Murray Darling Basin which revealed that the economic costs of salinity had been greatly underestimated. Over 2.5 million ha of former agricultural land in Australia are now unusable because of dryland salinity. The cost to the Australian economy is nearly Aus.$1 billion a year, or triple previous estimates. At least 80 towns and cities in regional areas are currently threatened by salt. 20% of South Australia s surface water is too salty for human consumption. Western Australia is losing the use of an area the size of a football field every hour due to salinity and its biodiversity is under threat.

Coping with salinity will be a long slow process. Potential remedial measures include widespread adoption of salt tolerant plants, drainage and diversion of saline water, and planting of deep-rooted perennials, especially along aquifer recharge sites identified through remote sensing and ground control. Australia s dryland salinity problem is a classic example of a creeping environmental problem akin to the progressive desiccation of the Aral Sea (Glantz, 1999).

LESSONS LEARNED FROM DESERTIFICATION

The social, economic and political background to the examples discussed above may differ greatly, but they have four common attributes. First, indiscriminate destruction of the native vegetation has resulted in severe and widespread land degradation by water, wind or salt. Second, the repercussions of this degradation extend well beyond the immediate area prone to desertification. Third, the initial causes of the desertification go back in time for decades or scores of years. Fourth, the onset of degradation was gradual and the resulting loss of productive land was at first almost imperceptible except to a few prescient and acute observers (Glantz, 1999).

DVI (Dust Veil Index)

The DVI is a measure of climatic effectiveness that was formulated in 1963 by H H Lamb of the British

Meteorological Office. DVI is used to compare the magnitude of volcanic eruptions by measuring the volume of dust and aerosols lofted into the atmosphere by a volcanic eruption and determining its influence on climate. Lamb s principle was that the rays of the sun are inhibited by the volume of dust emitted in an eruption. The climatic effectiveness of any single volcanic eruption may therefore be assessed by calculating its dust or tephra output. Lamb further suggested that stratospheric circulation would move dust from low latitude eruptions around the world while dust from high latitude eruptions would remain in the hemisphere of origin. Different climatic impacts were therefore modeled for eruptions which occurred at different latitudes and longitudes. Besides the latitude of eruption, the following additional parameters were incorporated; the residence time of the dust in the atmosphere, the dust cloud size, the maximum deviation from average temperature and the greatest depletion of incoming solar radiation. By concentrating on the dust volume emitted by different eruptions and by assigning a DVI of 1000 to the 1883 eruption of Krakatau, Lamb constructed a chronology of eruptions. DVIs were calculated for eruptions occurring from 1500 through to 1983. The volume of dust emitted in an eruption was correlated with available temperature records and Lamb s research suggested a correlation between low temperatures and a DVI 100. Importantly, there is a correlation between high DVI values and climatic cooling. His work showed the importance of documenting both volcanic eruptions and climatic anomalies.

The DVI can be calculated in the following three ways based on:

1. the depletion of radiation following the eruption;
2. temperature variations following the eruption; and
3. the amount of solid material dispersed as dust after an eruption.

It is calculated to be:

1. $\mathrm{DVI} = 0{\bullet}97RD_{\max}E_{\max}t_{\mathrm{mo}}$;
2. $\mathrm{DVI} = 52{\bullet}5Td_{\max}E_{\max}t_{\mathrm{mo}}$; and
3. $\mathrm{DVI} = 4{\bullet}4qE_{\max}t_{\mathrm{mo}}$.

$RD_{\max}$ is the largest percentage depletion of direct solar radiation indicated by the average monthly temperatures for the hemisphere concerned; $E_{\max}$ is the largest proportion of the earth affected by the dust veil; $E_{\max}$ is 1 for eruptions between 20° latitude north and south, 0.7 for eruptions between 20 and 35° north and south, 0.5 for eruptions between 35 and 42° north and south, and 0.3 for eruptions occurring above 42° latitude; $Td_{\max}$ is the estimated average lowering of temperature for the most affected year over the middle latitudes of the hemisphere affected; q is the estimated volume in cubic kilometers of solid matter injected into the atmosphere and t_{mo} is the atmospheric residence time for the dust.

Lamb considered that eruptions having a DVI = 100+ were capable of significant impact on climate. Since DVI is a form of prediction of climate change due to eruptions, the higher the DVI measurement of a volcano, the greater the effects of the eruption are on climate. For example, the Tambora eruption in Indonesia possessed a DVI of 1500, which indicates extremely high effects on climate, conversely Mount St Helen s in the US possessed a DVI of only one.

PROBLEMS WITH DVI

As a potential eruption estimate for climate disruption, the DVI is inadequate. It over-emphasizes the significance of the dust output and uses a circular argument to establish the relationship between climatic flux and eruption magnitude. Importantly, the problem is that accurate and precise temperature records do not exist before the 17th century and reliance on observations of climatic severity may be misleading. Moreover, DVI is dependent upon estimates of variable quality and involves the circularity of argument. This means that any temperature deviation from the norm is directly related to the size of an eruption and not to any other external forcing factors such as variation in the output of energy from the sun or fluctuations in the earth s orbit (circular argument).

Problems also lie in the use of Lamb s indices. Values of R, T, and t are calculated from mid-latitude observations, not necessarily where the maximum effect of a low or high latitude eruption would be experienced. Calculating the DVI of an eruption based on recorded values of T (temperature lowering) may be an inconclusive argument. Of Lamb s 250 DVI estimates only 10% were based on measured observations of a decrease in solar radiation or temperature decrease while 48% were based on non-quantitative descriptions of eruptions such as personal accounts and observations. Consequently, it is simply not safe to assume that all temperature departures in eruption years are the result of volcanic activity. Problems also lie in the use of an inadequate eruption chronology, and in the assignment of values for $RD_{\max}$ (greatest depletion in solar radiation) and $E_{\max}$ (latitudinal dispersal of the dust cloud) from proxy records. Inadequate data exist from which to assign a DVI to eruptions prior to the 19th century, or to small eruptions or where several eruptions were closely spaced. As a result there is a risk of entering into a circular argument where temperature declines are used to support estimates of the value of $RD_{\max}$ ($Rd_{\max}$ reflects the greatest depletion in solar radiation) equated as the degree of eruption magnitude. Temperature deviations in eruption years should not be assumed to be the result of volcanic activity. Importantly, temperatures from observations made in a continental interior may not be relevant for the continental fringe and *vice versa*. Estimates of $E_{\max}$ fail to take

into account the possibility of other phenomena such as dust storms being interpreted as being of volcanic origin and problems with D_{max} that is the measure of the degree of eruption magnitude.

APPLICATIONS

An early attempt to refine the use of DVI as a major climatic forcing mechanism was made by Cronin in 1971 by investigation of the periodicity with which volcanoes erupted in the mid-20th century. Unfortunately, several significant eruptions were ignored, importantly the Alaska eruptions of Trident in 1952 and Spurr in 1953. Yet, it was observed that volcanic eruption in lower latitudes where the stratosphere is higher had a greater climatic impact than the eruption of volcanoes at high latitudes where the stratosphere is lower.

In 1974, Bray used DVI in an attempt to correlate volcanic activity and glacier response in the Northern and Southern Hemispheres over the past 40 millennia. It was discovered that the DVI was inadequate as a measurement tool to account for glaciers and climate change. The resultant inconsistent glacier response time indicated further problems with the use of DVI. For further clarification, Bradley and England in 1978 investigated glacier response and significant DVI events. They concluded that DVI was an inadequate measure of climatic effectiveness of a volcanic eruption. Other estimate methodologies of magnitude, the Volcanic Explosively Index (VEI) and the Ice-core Volcanic Index (IVI), were subsequently developed because of several failings of DVI. The DVI was later replaced by the VEI (*see* VEI (Volcanic Explosivity Index), Volume 3).

Earthquake Intensity and Magnitude Scales

Earthquakes are rated on two different scales: an intensity scale and a magnitude scale. An intensity scale is useful in classifying and describing damage to terrain and buildings following earthquakes. The arbitrary *Mercalli scale*, expressed in Roman numerals from I to XII, indicating conditions from barely felt to catastrophic total destruction, is used to represent intensity. Earthquake magnitude is estimated according to a system developed by Charles Richter in 1935. Richter established an open-ended, logarithmic scale in which each whole number represented a 31.5-fold increase in the amount of energy released by the earthquake. Thus, 4.0 on the Richter scale represent 31.5 times more energy than 3.0 and 992 times more energy

Table 1 Effects of earthquakes, intensity and magnitude scales and their approximate frequency

Effects in populated areas	Approximate intensity (modified Mercalli scale)	Approximate magnitude (moment-magnitude scale)	World total number year^{-1}
Nearly total damage	XII	>8.0	1 every few years
Great damage	X–XI	7–7.9	18
Considerable to serious damage to buildings; railroad tracks bent	VIII–IX	6–6.9	120
Felt by all, with slight damage to buildings	V–VII	5–5.9	800
Felt by some to felt by many	III–IV	4–4.9	6200
Not felt, but recorded	I–II	2–3.9	500 000

than 2.0. A *moment-magnitude scale* has now replaced the *Richter scale* because it is regarded as more accurate than Richter s amplitude-magnitude scale for large earthquakes. Moment magnitude considers the amount of fault slippage produced by the earthquake, the area of the surface (or subsurface) that ruptured, and the nature of the materials that faulted, including how resistant they were to failure. The basis of the intensity and the moment-magnitude scales, as well as values for some major natural earthquakes, are set out in Tables 1 and 2.

IAN DOUGLAS *UK*

Earthquakes Triggered by Human Activities

Ian Douglas
University of Manchester, Manchester, UK

Varying amounts of evidence indicate that several types of engineering and extractive industry activities are suspected of triggering limited localized earthquakes known as induced seismicity. Examples include increased or accelerated activity in seismically active areas or the onset of seismicity in aseismic areas. Earthquakes occur whenever the stresses acting on a point in the lithosphere exceed the strength of rock at that point. Most natural earthquakes occur on pre-existing cracks or fractures where the rock is weakest.

The scienti c study of induced-seismicity began when earthquakes started to be felt in Johannesburg in 1894. By 1908 it was recognized that the gold mining initiated in 1886 was causing these events. The earth movements in this naturally highly stable area increased as the mines became deeper and disturbed the stress eld in the Archean rocks.

Such environmental changes are signi cant because:

1. *much of the earth's lithosphere is stressed near to its failure strength so that even small perturbations in the stress state may lead to induced seismicity;*
2. *many of the induced events occur close to the structures or enterprises that cause them. Thus quite small movements may cause important, economic, social and environmental changes;*
3. *some events can be large causing widespread damage.*

The main causes of induced seismicity are:

1. *reservoir storage: the impounding of large amounts of water behind dams;*
2. *extraction of minerals: quarrying at the surface, shallow mine workings, deep underground workings;*
3. *detonation of underground explosions;*
4. *uid removal: the extraction of oil or the pumping of water from an aquifer;*
5. *uid injection: the injection of high pressure uids into the ground, as in solution mining, waste disposal, geothermal power exploitation, and secondary oil recovery.*

RESERVOIR STORAGE

Reservoir-induced seismicity (RIS) may be divided into three classes:

1. No change in seismic activity;
2. Micro earthquakes, the frequency of which increases with initial inundation and thereafter varies according to water level variation. These tremors eventually subside;
3. Micro earthquakes, the frequency of which increases with the initial inundation and thereafter varies according to water level variation above a threshold value. Subsequent to this, medium size earthquakes may occur, followed by micro earthquakes and eventually stabilization.

Reservoir-induced earthquakes tend to occur close to the reservoir and to have small focal depths. The frequency of small earthquakes is higher than that of large ones and there is a high chance of occurrence in an area of normal or lateral faults. Medium sized earthquakes tend to occur in situations where the height of the dam exceeds 90 m, the stored volume of water is large, typically over 1 km^3, and locally the rocks have many fissures and faults in the crust. The increase in local seismic activity may lead to consequences ranging from numerous small stress-relieving earthquakes to catastrophic earthquakes and slides similar to the events in 1967 that destroyed India s Koyna Dam and resulted in a significant number of deaths.

Most reservoir seismicity is small and as yet there have been only 4 cases which have exceeded moment magnitude scale level (M) = 6:

1. Koyna, India, 1967, M = 6.3
2. Hsinfengkiang, China, 1962, M = 6.1
3. Kariba, Zambia/Zimbabwe, 1963, M = 6.1
4. Kremasta, Greece, 1965, M = 6.2

The Koyna earthquake in Maharashtra state, on December 10, 1967 (M 6.3) is the largest and most damaging reservoir-induced earthquake so far, claiming over 200 lives, injuring over 1500, rendering thousands homeless, and destroying much of the infrastructure in the Koyna Nagar town. The region south of the Shivaji Sagar reservoir has the highest reservoir-induced seismicity (RIS), with more than 150 events of magnitudes M_L 4.0 occurring from 1962 to 1996, of all open water storage reservoirs in the world. The activity is still continuing. Remarkably, most of the earthquakes are concentrated in a 25 km × 40 km area (Gupta, 1992; Gupta *et al.*, 1997). In the 1990s, a second reservoir, the Warna, one-third the size of the Shivaji Sagar reservoir, was completed some 30 km south of the Koyna Dam. It also appears to have created considerable RIS (Gupta *et al.*, 1997).

Seismicity started only a month after water began to be stored behind the 105 m high Hsinfengkiang dam in China in 1959. During the first few months seismicity increased as the water level rose. The main shock of 1962 occurred in an area where north-northwest faults intersected an east-northeast fault system. The local rocks have well developed joints. The main shock created cracks in the dam itself, the riverbank and local buildings. All events occurred within 5 km of the reservoir.

In 1958 Lake Kariba became the largest sustained artificial increase in loading on the earth s crust as it filled with water slowly from 1958 1963. In 1963 several large earthquakes occurred near the deepest portion of the reservoir (Meade, 1991). The earthquake mechanism was dip-slip on normal faults. Later earthquakes in the area, in 1966 1968, appear to have been unconnected with the reservoir.

The level of the Kremasta reservoir in Greece was repeatedly lowered and raised between 1967 and 1972. Careful observations by the project engineer showed that these fluctuations corresponded with levels of increased seismic activity (Therianos, 1974).

EXTRACTION OF MINERALS

Seismicity is primarily caused by changes in the elastic stress resulting from the removal of large masses of rock in mining and surface quarrying. Mining-induced seismic events arise from the redistribution of stress caused by large-scale mining. The total stress state around a mine excavation is the sum of the ambient stress state in the rock mass and the stresses induced by mining. The ambient stress is lithostatic corresponding to the weight of the overburden. Hence there is an increase in stress with depth. This is dangerous not only for those underground, but also causes subsidence. Mining-induced earthquakes of M = 5.7 have been associated with potash workings, while subsidence is particularly frequent in areas of underground salt extraction.

At a quarry in Wappingers Falls, New York, a shallow, 0.5 to 1.5 km deep earthquake sequence occurred in 1974 with a main shock of magnitude M = 3.3. These thrust earthquakes were located directly below the floor of the quarry which had been worked for 75 years down to a depth of 50 m, providing a stress change, albeit over many years, of 1.5 megapascals (MPa). As this region is an area of high horizontal compression, removal of surface material equated to reducing the normal stress. This led to the appearance of pop-up structures in the quarry floor as is often found in the eastern US.

DETONATION OF UNDERGROUND EXPLOSIONS

Underground explosions, as in deep mines also cause local changes in stresses in the rocks, which affect the stability of mine workings, and the overlying rocks.

FLUID REMOVAL

Since 1970 several small earthquakes have occurred in the Western Canada Sedimentary Basin. Many of the epicenters are shallow and are situated near areas of oil and gas production in the western side of the basin. The earthquake of October 19th, 1996, in the Strachan Field, in the Alberta foothills southwest of Rocky Mountain House was most probably triggered by gas extraction.

FLUID INJECTION

The major influence of fluid injection on the stress field is to increase pore fluid pressure. When fluid enters a fracture, it supports part of the normal stress equivalent to the pressure of the fluid. As the fluid has no shear strength, the effective normal stress and the frictional resistance to sliding are reduced. Any earthquakes so caused tend to be small and cause little damage.

The US Army injected chemical waste under various pressures into a waste disposal well drilled into crystalline basement rocks at their Rocky Mountain arsenal from March 1961 to February 1966. A sudden increase in seismic activity in this not usually earthquake prone area suggested that the fluid injection was causing earth tremors. Eventually a linear trend of seismic activity for 5 km from the well became apparent. Events of M = 4.8 5.2 in 1967 caused damage to windows, water pipes, roads and cracking

in concrete pillars. Those events caused $0.5 million of damage, with a total of $8 million damage over the period of pumping.

IMPLICATIONS FOR GLOBAL ENVIRONMENTAL CHANGE

While no one of these induced seismic events will have a global impact, the great 20th century upsurge in all the types of activity producing induced seismicity means that ground disturbance due to engineering works and minerals extraction is becoming an increasing local environmental threat. Now the possibility of induced seismicity is being considered as part of the environmental risks associated with major mining and reservoir projects. For example, although only three unequivocal cases of RIS have been established in Australia, the Talbingo reservoir in New South Wales, the Gordon dam in Tasmania and the Thomson reservoir in Victoria, seismic observations are being made at such reservoirs as the Wivenhoe, Burdekin Falls, Boondooma and Awoonga dams in Queensland (Cuthbertson).

Events at the induced seismicity scale can disrupt local utility infrastructure, especially pipelines and drains and may weaken such structures and river embankments and flood defenses, thus potentially aggravating the impacts of extreme events whose frequency may be heightened by global warming. As with other people-driven impacts on the environment, these cases of induced seismicity have to be seen as part of a cumulative series of small changes which together affect ecosystems and human living conditions.

Ecological Capacity

William E Rees
University of British Columbia, Vancouver, Canada

Super cially, the concept of human carrying capacity seems fairly straightforward - but consider the following. In 1986, ecologist Garrett Hardin wrote: " The na¨ve question, 'What is the human carrying capacity of the earth?' evokes a reply that is of no human use" (Hardin, 1986). Yet, in 1991, the same author declared that " carrying capacity is the fundamental basis for demographic accounting" (Hardin, 1991). What new evidence had come to light in the intervening ve years? Why had Hardin seemingly changed his mind? Well, there was no new evidence and Hardin's position actually remained rm. The fact is there is no real contradiction between the two statements. Hardin was right in both cases.

*How can we explain this apparent paradox? It seems that the human carrying capacity conundrum resides in certain qualities unique to our species. For other organisms, carrying capacity (*see *Carrying Capacity, Volume 4) is usually de ned as the maximum population that can be supported inde nitely in a de ned habitat without permanently impairing the productivity of that habitat (with allowances for climatic vagaries and other random events) (Rees, 1996; Kirchner* et al., *1985; Meadows* et al., *1992). This de nition is conceptually adequate for game and range management which is concerned with deer, antelope, or cattle. The demands of these animals on their ecosystems are xed and limited to food and shelter, the simplest of material requirements. But humans are hardly simple and present numerous novel challenges to demographers and human ecologists.*

To begin, humans are large omnivorous mammals who live in social groups, so even our basic demands are challenge enough for most natural ecosystems. Moreover, the situation is uniquely complicated because human demands have never been limited to the basics and are constantly increasing. This is because humans are creatures of culture, language, cumulative knowledge and social adaptation. Particularly since the scienti c revolution in the 16th and 17th centuries, human social organization and technology have enabled us gradually to restructure the environment

in the service of ever increasing numbers of people. By the full owering of the Industrial Revolution in the 19th century, we seemed to have gained the power to expand human carrying capacity virtually at will. The global population almost twice doubled to six billion people in the 20th century and resource consumption continues to balloon vastly faster. As a result, humans have become the equivalent of a geological force in changing the face of the Earth. Most signi cantly, the scale and quality of our impact has long been determined more by prevailing values, social behavior, and technology than by mere biophysical needs. This is why Hardin seemed to dismiss " what is the human carrying capacity of the Earth?" as a na¨ve question in 1986.

It is also why the notion of human carrying capacity - of meaningful limits to growth - has no credibility in the important corridors of global power. International organizations and national governments everywhere are dedicated to the proposition that human wellbeing in both the rich and poor countries is tied to maintaining the spiral of continuous economic expansion. Nevertheless, with the acceleration of human-induced (if not human-controlled) global change, it does seem fair to ask whether this vision is sustained as much by the weight of evidence as it is by mere techno-hubris. Are humanity's unique attributes really suf cient to free us forever from the constraints of carrying capacity that seem so rmly to bind all other species? Hardin's answer in 1991 was unequivocal - living within carrying capacity remains fundamental to long-term human welfare.

Continuous advances in technology and the human predisposition to trade are usually cited as reasons for rejecting the notion of human carrying capacity out of hand. Any human population (e.g., a region or country) that can trade surpluses of resource A for needed supplies of resource B need not be restricted in population or economic growth by the theoretical carrying capacity of its own territory. Technology further enables modern humans to reduce or eliminate many of the natural negative feedback mechanisms (such as disease and famine) that limited population growth in earlier times. In general, because humans are toolmakers, we are capable of squeezing more out of [our] environment than undisturbed nature would provide . . . so that the capacity of a given environment to support human populations can expand relatively rapidly (Demeny, 1988). According to some authors: Because of increases in knowledge, the earth s carrying capacity has been increasing throughout the decades and centuries and millennia to such an extent that the term carrying capacity has by now no useful meaning (Simon and Kahn, 1984).

Well, perhaps. Certainly human technological prowess has enabled our species to spread over virtually the entire planet. We have increasingly replaced the natural landscapes of Earth with cultural landscapes dedicated to the human enterprise. By the mid-1980s, Vitousek *et al.* (1986) estimated that humankind was already appropriating, directly and indirectly, almost 40% of the products of net terrestrial primary production. Similarly, the global fishing fleet appropriates seafood for humans that represents 25 35% of net marine primary production in the shallow coastal shelves and estuaries that produce 96% of the catchable fish in the sea (Pauly and Christensen, 1995). Through technology, humans have apparently become the dominant consumer organism in most of the major ecosystem types on the planet.

Of course, no one argues that all this progress comes without a cost. Even in the Neolithic, the invasion of new habitats by humans invariably resulted in local extinctions of easily hunted species; and in technologically augmented modern times we are witness to widespread fish stock collapses, deforestation, accelerating biodiversity loss, soil degradation, falling water tables, atmospheric change, and generalized pollution of air, water, and soil, all on a global scale. All the same, according to conventional wisdom, there is no cause for alarm. Mainstream economists argue that pollution can be managed by outright bans where necessary (e.g., ozone depleting chemicals) or by correcting for market failures through pollution charges and tradable pollution rights that internalize the externalities. As for resource depletion, this poses even less of a problem to technological optimists. They argue that human ingenuity has found functional substitutes for many declining resources over time (petroleum for coal, optical fiber for copper wire, etc.) and there is no reason why this shouldn t continue indefinitely. As Nobel Laureate economist Robert Solow wrote in 1974: If it is very easy to substitute other factors for natural resources, then . . . the world can, in effect, get along without natural resources, so exhaustion is just an event, not a catastrophe (Solow, 1974).

Indeed, belief in near perfect substitution has become a central tenet of neoclassical economics in recent decades. Some adherents even proclaim that resources are more the product of the human mind than they are of nature. In 1990, Walter Block, then Senior Economist at the Fraser Institute (a conservative think tank in Vancouver), argued the benefits of continuous population growth on grounds that additional people can create more resources than they use up, thanks to technological improvements . . . (Block, 1990). More recently, the University of Maryland s late famed growth advocate, Julian Simon, wrote: Technology exists now to produce in virtually inexhaustible quantities just about all the products made by nature . . . , and: We have in our hands now . . . the technology to feed, clothe, and supply energy to an ever-growing population for the next seven billion years . . . (Simon, cited in Bartlett, 1996; see also Simon and Khan, 1984). If this were true and human numbers the only consideration, carrying capacity

would indeed be a non-issue and Malthus ghost could surely take its final rest. But Professor Simon s statement could hardly be further from truth. Under pressure, Professor Simon later corrected his statement to read ... for seven million years . However, as physicist Albert Bartlett (1996) has shown, just 1% annual growth over this much reduced time-frame would result in a human population 30 000 orders of magnitude larger than the estimated number of atoms in the known universe! Simon had obviously not done the math.

CARRYING CAPACITY AS MAXIMUM HUMAN LOAD

> An environment s carrying capacity is its maximum persistently supportable load.
>
> (Catton, 1980)

There is another way of looking at human carrying capacity that enables us to interpret the techno-optimists view of the effects of trade and technology in quite a different light. Because of the variability in human demand, Catton (1980) argued that it makes more sense to define human carrying capacity not as the maximum sustainable population, but rather as the maximum load that can safely be imposed on the ecosphere by people. Total human load is clearly a function not only of population but also of *per capita* consumption, and the latter is increasing even more rapidly than the former due (ironically) to expanding trade and technology. In effect then, Catton is arguing that the world is being required to accommodate not just more people, but effectively larger people. To illustrate, in 1995 the extra-somatic energy being used *per capita* in rich countries like the United States and Canada, was equivalent to the work that might be done by up to 200 ghost slaves (Price, 1995). As a result of such trends, we can argue that load pressure relative to load-bearing capacity is rising much faster than is implied by mere population increases.

One way to estimate the human load on the ecosphere is through *ecological footprint analysis*. This method converts the material demands and impacts of a study population into its land/water area equivalent (Rees and Wackernagel, 1994; Rees, 1996; Wackernagel and Rees, 1996). Thus:

> The ecological footprint of a specified human population is the total area of land and water (ecosystems) required on a continuous basis to produce the resources that the population consumes, and to assimilate the wastes that the population produces, wherever on Earth the relevant land/water is located.

In practice, only a limited range of waste discharges can be readily converted to an areal equivalent, so calculated eco-footprints are underestimates of total load. Nevertheless, the most recent studies show that typical eco-footprints range from less than a hectare per person in poorer countries like India to seven or even ten hectares per person in high income countries like Canada and the United States (Wackernagel *et al.*, 1999). (Note that there are only about two hectares per person of ecologically productive land and water on Earth, so wealthy consumers are unwittingly appropriating more than their fair share of global ecological output.) Such data reveal not only the contribution of resource consumption to human load but also the prevailing inequity across income levels.

Significantly in the present context, the eco-footprint of the present global population of six billion is already as much as 30% larger than the planet the human load has already overshot the long-term carrying capacity of Earth (Figure 1). Indeed, at least two additional Earth-like planets would be required to support just the present world population sustainably if everyone enjoyed Western European material standards. Widespread ecological degradation indicates that even at current average consumption levels, we are living by drawing down cumulative stocks of *natural capital* (*see* Natural Capital, Volume 2) that cannot be replaced in any meaningful human time frame. According to some authors, the apparent expansion of human carrying capacity therefore cannot be permanent (Catton, 1980).

Other studies based on material flows have reached similar conclusions. Using readily available data on waste discharges and on the *assimilative capacity* (*see* Maximum Sustainable Yield (MSY), Volume 4) of biophysical

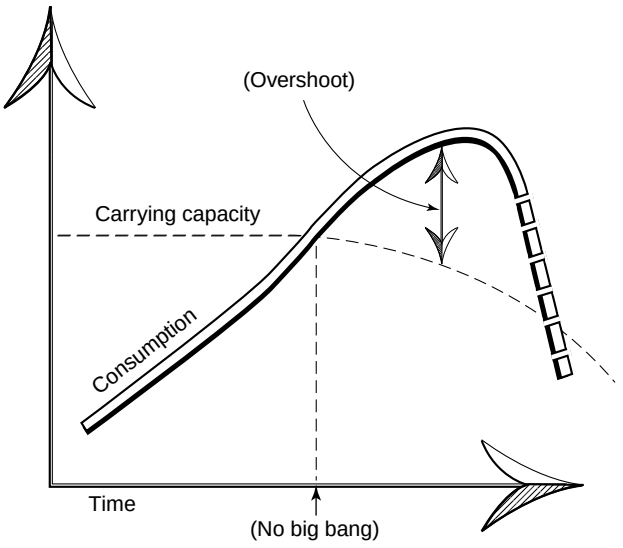

Figure 1 Overshoot is population and economic growth beyond long-term carrying capacity. One effect is accelerating degradation of habitat and supportive ecosystems, i.e., the reduction of future load-bearing capacity. Eventually, the population must come down. The relevant question is, will humanity manage a soft landing or must we suffer an uncontrolled crash. (Drawing by Phil Testamale; *Source:* Wackernagel and Rees, 1996)

systems, the Sustainable Europe Campaign has estimated that sustainability requires an approximately 50% reduction in the material throughput of the global economy in coming decades (Carley and Spapens, 1998). However, in order to create the necessary environmental space for developing countries to claim their fair share of global carrying capacity, developed country reductions in the use of non-renewable resources range between 88 and 94%. Even the World Business Council for Sustainable Development (WBCSD) seems convinced that: Industrialized world reductions in material throughput, energy use, and environmental degradation of over 90% will be required by 2040 to meet the needs of a growing world population fairly within the planet s ecological means (WBCSD, 1993) (*see* WBCSD (World Business Council for Sustainable Development), Volume 4). The need for a tenfold reduction in resource consumption by high income countries is confirmed by the United Nations Environment Programme s (UNEP) Global Environment Outlook 2000 report (UNEP, 1999).

Total human load also exceeds global carrying capacity by other criteria. So far the discussion has been totally anthropocentric. What about other organisms? We have noted that humans appropriate almost half of the products of terrestrial photosynthesis and 35% of marine primary production for themselves. Obviously, production that humans take for their own use is irreversibly unavailable to other species (this is a variation on the competitive exclusion principle). Every additional person, house, automobile, etc., therefore reduces in some measure the capacity of the planet to support other life-forms. In short, as people take over more and more forest, grassland, and other natural habitats for their own purposes, they invariably contribute to a loss of biodiversity including the irreversible loss of other species. The seeming increase in human carrying capacity (as measured by human numbers) is thus accompanied by a decrease in ecosystems capacity. Indeed, habitat takeover combined with overharvesting and pollution are producing what some analysts are calling the sixth extinction (the first 5 extinctions are discussed in Extinctions and Biodiversity in the Fossil Record, Volume 2). The current extirpation rate is 100 1000 times pre-human levels inferred from the fossil and paleontological record (Pimm *et al.*, 1995).

To some, this provides moral or ethical grounds for claiming that people have long since exceeded global carrying capacity. So called deep ecologists, many conservationists, and ordinary people who simply love nature, believe that other species have intrinsic value quite apart from their utility to humans. From this perspective, the millions of other life forms with whom we share the planet have a right to exist and people have no right to take more from nature than they need for material sufficiency. Growth in human numbers and consumption to the point where it destroys the integrity of ecosystems and eliminates species is seen as inherently immoral. By this criterion, we breach human carrying capacity when population or economic expansion compromises the survival of other life forms.

Where does all this leave expansionist economists and other techno-optimists? Again, there is no doubt that advances in technology have enabled the continued expansion of human populations. However, this apparent increase in short-term carrying capacity has actually been accompanied by a real reduction in long-term load-bearing capacity. Technology creates seeming abundance by increasing both the intensity and spatial scale of humanity s exploitation of the ecosphere. Sometimes humans gain by appropriating the habitats and ecological niches of other species at great cost to systems integrity. Sometimes technology is used to accelerate the energy and material flux

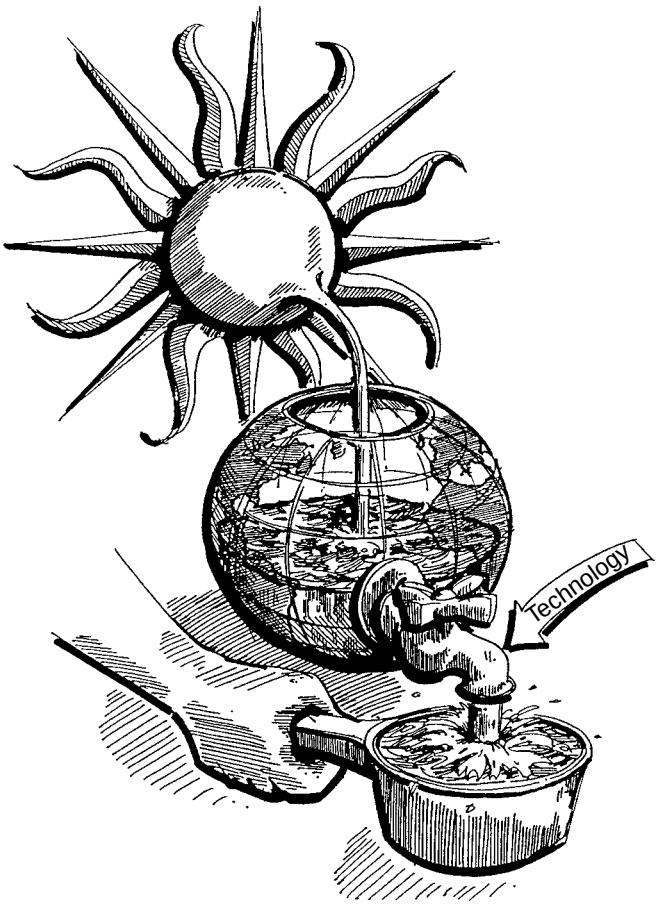

Figure 2 To date, technology has been used largely to accelerate the intensity and rate at which human beings appropriate both renewable and non-renewable resources. Sustainability demands that essential stocks of natural capital not be exploited beyond rates of renewal/replacement and that waste production not exceed the assimilative capacity of ecosystems. (Drawing by Phil Testamale; *Source:* Wackernagel and Rees, 1996)

through exploited ecosystems (Figure 2). In either case, short-term gains in systems productivity permanently erode the resource base and with it the life-support functions of the ecosphere. Energy-subsidized intensive agriculture may be more productive than low input practices in the short-term, but it also increases the rate of soil degradation and groundwater depletion (*see* Agricultural Intensi cation in Western Europe, Volume 3). Similarly, the effectiveness of electronic fish finding devices and high-tech fishing gear overwhelms the reproductive capacity of commercial fish stocks (*see* Changes in World Marine Fish Stocks, Volume 3). The net effect is that more and more people are increasingly dependent on technologically enhanced but potentially unsustainable material flows. Why unsustainable? The technologies themselves are usually based on non-renewable resources (e.g., fossil fuel), and the ecosystems, already over exploited, are now further stressed by human-induced global (e.g., climate) change.

At its best, technological innovation can improve the efficiency of resource use, but again this does not increase load-bearing capacity *per se*. In theory, shifting to more energy and materially productive technologies should enable a defined environment to support a given population at a higher material standard, or a higher population at the same material standard, thereby seeming to increase carrying capacity. However, in either case, we are simply maintaining total human load constant in the vicinity of load-bearing capacity the latter is still ultimately limiting. In practice, we have not done even this well. The steady gains in material efficiency in the post World War II period have been accompanied by increasing *per capita* and aggregate consumption (WRI, 2000). It seems that efficiency gains may actually work against conservation by raising incomes and lowering prices. This gives people more money to spend on cheaper goods and services so total throughput human load has steadily expanded.

The carrying capacity gains from trade are also often illusory. Wealthy nations can exceed domestic limits to growth only by appropriating carrying capacity from the global commons or from other countries all over the world. While commodity trade releases local populations from local resource constraints, it merely displaces some fraction of that population s biophysical load to distant export regions. The resultant increase in population and consumption in importing regions increases the total load of people on the ecosphere but there is no net gain in carrying capacity since trade often reduces the load-bearing capacity of the export regions. Indeed, like technology, trade may even result in lower global load-bearing capacity. Access to cheap imports (e.g., food) may reduce the incentive for importing regions to conserve local natural capital stocks (e.g., agricultural land). Meanwhile, trade accelerates the depletion of natural capital soil, water, forests, biodiversity in the exporting regions, as producers struggle to compete in the global marketplace.

CONCLUSIONS: LIGHTENING THE LOAD TO SOFTEN THE CRASH

Technology and trade have unquestionably enabled the vast expansion of the human enterprise. But it is a confusion of logic to equate the increase in numbers and economic scale with an increase in load-bearing capacity of the earth. The main effect of technology and trade to date has been to enable humans to extend the area and depth of their ecological footprints all over the planet at the expense of other species and the overall integrity of the ecosphere. Far from having been freed from biophysical constraints, people in high income countries today are arguably more indebted than ever to nature and increasingly vulnerable to rapid global change.

So perhaps human carrying capacity ought to be the fundamental basis for demographic accounting after all. There may be any number of different sustainable human populations depending on prevailing values, material standards and technological sophistication. However, for sustainability, any population must live within the *load-bearing capacity* of the planet.

Where do we stand today? The empirical evidence suggests that with present beliefs and prevailing technologies, the existing human population has already significantly overshot global carrying capacity. Unfortunately, because populations in overshoot live partly by depleting even their renewable resource system, they also reduce the future life support capacity of their habitat. Some researchers therefore conclude that the life expectancy of our western techno-industrial society is less than 100 years (Duncan, 1993) and that it will necessarily self-destruct, producing massive ecological damage, social chaos, and megadeath (Smith and Sauer-Thompson, 1998; see also Catton, 1980; Price, 1995; Lyons *et al.*, 1995; Smith *et al.*, 1997).

If we are even to soften what so many see as the inevitable crash, technology must assume a more constructive role. For people to live sustainability within the biophysical carrying capacity of Earth in the 21st century, there must be dramatic reductions in energy and material consumption. Researchers in Europe and North America are calling for a *factor-four* (double the output with half the resources) (Ayers, 1998; Weizsacker *et al.*, 1997) and even a factor-ten revolution in resource productivity (WBCSD, 1993; UNEP, 1999), and are lobbying for the fiscal and economic policies needed to make it happen.

But more efficient technology is not the only way humans can increase their numbers without increasing their load on the Earth we can also adapt behaviorally. Suppose

the increasing stress and spiritual emptiness of consumer society results in the voluntary simplicity movement really catching on in the developed world (increasing numbers of people are, in fact, trying to create meaning in their lives beyond the accumulation of stuff by taking time to rediscover their communities, their families, and themselves). To the extent that materially simpler but spiritually richer living reduces energy and material consumption, the eco-footprints of the world s wealthy would shrink. This in turn would create more ecological space for the poor particularly in the developing world to increase their consumption to an acceptable standard.

Certainly simply to maintain our present course would be a dangerous strategy. Complex systems theory (and an increasing number of real world disasters) suggests that biophysical systems under stress become increasingly brittle. As we push the ecosphere, the oceans, and the atmosphere to their limits, they are likely to exhibit erratically unpredictable or even catastrophic behavior (*see* Monitoring in Support of Policy: an Adaptive Ecosystem Approach, Volume 4). The sudden collapse of fisheries and accelerating climate change may be signals that we are close to the edge of such systemic chaos on a global scale. Thus, for all the apparent success of technology in freeing us from the whims of nature, if the human population and the material economy continue to expand, there is a finite possibility that we could actually be on the verge of extinction, blissfully unaware that a mathematical fiction in the space of the possible is about to become reality. And the really nasty feature is that that may take only the tiniest of changes to trigger the switch (Cohen and Stewart, 1994, 212).

Ecological Footprint

Ecological footprint analysis is usually applied to discrete human populations. The *ecological footprint* of a specified population is the total area of land and water ecosystems required on a continuous basis to produce the resources that the population consumes, and to assimilate the wastes that the population produces, wherever on Earth the relevant land/water is located. Thus, the eco-footprint calculation is usually based on a specified population s current final demand for goods and services and represents the total load that the study population imposes on the ecosphere. Sometimes, however, it is instructive to eco-footprint particular industries or economic activities. For example, we can use eco-footprint analysis in comparative technology assessment to contrast the relative ecosystem requirements of alternative production technologies or processes.

Ecotoxicology

Ecotoxicology, combining ecological and toxicological knowledge, was defined in the early 1970s as the branch of science concerned with the toxic effects of chemical and physical agents on living organisms, especially on populations and communities within defined ecosystems, and including the transfer pathways of those agents and their interactions with the environment. It does not cover, as a rule, the study of toxic effects on humans or domesticated animals, which is the object of toxicology, but has in its purview the environmental pathways of toxicants to humans.

Ecotoxicological knowledge is the basis for the ecological risk assessment of chemicals and physical agents. *Risk* is defined as the probability of occurrence of damage or undesirable effect resulting from exposure to a hazardous substance or agent. *Exposure* is the amount of the chemical or physical agent that reaches the target organism or population.

Consequently ecotoxicological research addresses quantitatively, in a logical sequence, the source term, i.e., the amounts, forms and sites of release of polluting agents; their transfer and transformations as they move among environmental compartments; the amounts reaching the identified biological targets (exposure and dose); and the response (dose effect relationship) of these organisms, populations, communities and ecosystems. This methodology was derived from previous studies on radioactive contamination caused by testing of nuclear weapons as well as by peaceful applications of nuclear energy, which is the subject of *radioecology*.

Ecotoxicology developed rapidly in the 1970s, with the increasing releases of pollutants from fossil fuels combustion and the use of synthetic chemicals. It was spurred by concern originating from the acidification of precipitation, lakes and soils (the acid rain problem), the effects of dichlorodiphenyltrichloroethane (DDT), pesticides and other synthetic chemicals on animal populations. Ecotoxicological research has produced detailed knowledge on the fate and effects of toxicants in the environment, which has been broadly used in defining policy measures such as ecological quality standards or pre-marketing ecotoxicity tests for new chemicals. It has also improved pollution monitoring, for instance through the use of bioindicators, which are organisms that concentrate pollutants, and biomarkers, or biochemical changes resulting from even very low-level exposure to specific chemicals. An ecotoxicological problem of great current interest is that of endocrine disrupters, which interfere with sexual expression, reproductive behavior, etc., of animals in aquatic ecosystems.

For an example of an ecotoxicological assessment, *see* Environmental Cadmium in the Food Chain, Volume 3. For an example of ecotoxicological method, *see* Use of

Epidemiological Data to Develop Air Quality Standards for Short-term and Long-term Environmental Health Bene ts, Volume 4.

Emergy

The leading American ecologist H T Odum developed the concept of *emergy* (Odum, 1988, 1991). He defines emergy as the energy of one type required in transformations to generate a flow or a storage (Huang and Odum, 1991) Emergy is thus the available energy of one kind previously used up directly and indirectly to make a product. Its unit is the emjoule. Since work is required to concentrate materials, higher concentrations of material require more emergy per mass. In other words, emergy is required to concentrate materials and keep them concentrated. The ratio of emergy to mass of materials is a useful measure of work that has been applied to materials. Emergy can be used to represent both the quality and the quantity of energy that any input or product of the economy represents. Furthermore, the emergy concept offers an alternative and complementary viewpoint of value on the biophysical nature of human activity (*see also* Emergy, Volume 5).

If the mining, processing and use of lead in an industrialized society is considered, processes within the earth system add emergy as they converge and concentrate heavy metals in making ore bodies during high temperature and pressure mountain building tectonic events. Human society adds emergy from fuels, machinery and human effort when it mines minerals, refines them and produces such products as lead acid batteries. The greater the work involved in concentrating lead, the higher the emergy per mass. Spatially, concentrations of lead are greatest in cities and along transportation corridors. On the other hand, as lead is dispersed in waste streams, the emergy/mass ratio decreases. In wetlands, the dispersed heavy metals get taken up by plants and then by microorganisms (Odum *et al.*, 2000).

Environmental Cadmium in the Food Chain

J Keith Syers[1] and Michael Gochfield[2]
[1]*Naresuan University, Phitsanulok, Thailand*
[2]*Rutgers University, NJ, USA*

Cadmium (Cd) is important because it is a toxic and carcinogenic element, which occurs widely in the environment, both from natural and anthropogenic sources. Cadmium has been linked to bone disease in Japan and more widely to renal functional abnormalities. The extent to which these abnormalities are clinically signi cant is an important issue, which has engendered substantial controversy and no consensus. Given these human health implications, it is essential that our understanding of cadmium in the environment be more precise.

An expanding world population places pressure on finite natural resources, particularly with regard to establishing world food security. Worldwide, food production growth has outstripped population growth largely due to technology, which has increased yields per hectare (ha). Progress has, however, been uneven and in many regions, significant numbers of people, particularly the poor, women and children, remain seriously malnourished. Nutrient inputs, from several sources, are an important contribution to increased food supply but can have some unintended, adverse effects on ecosystems and humans. Cadmium (Cd) is an impurity in all of these nutrient inputs and poses risks to ecosystems and the human food chain. These are often moderated and regulated by government intervention and policies which should not, however, jeopardize food security, particularly in the poorer parts of the world where population growth, hence the demand for food production, is highest.

Management of food safety to protect human health must be carried out in the wider context of two worlds, a smaller one with food security and current food surpluses, and a larger one with food shortages that are aggravated by rapid population growth and urbanization. The latter, primarily tropical, world is also one where environmental, agricultural, ecological and biomedical data relevant to cadmium and

other toxic substances are most meager and where concomitant health and nutritional stresses are greatest.

SOURCES

- Atmospheric cadmium is mainly derived from metal smelting, the uncontrolled burning of fossil fuels for energy, and incineration of solid wastes and sewage.
- Reducing emissions of cadmium to the atmosphere by improvement in pollution control devices, energy conservation, and the selection of low-polluting fuels must be pursued vigorously.
- Biosolids (sewage sludge) contain relatively small concentrations (mean $<10\,mg\,kg^{-1}$ dry matter (DM) in developed countries) but can add large amounts of cadmium to soil. The disposal of biosolids is therefore a major issue. Restrictions on dumping at sea will force a more extensive disposal of biosolids on land or increased incineration with concomitant release of cadmium to the atmosphere.
- Biosolids have beneficial attributes in improving soil structure and supplying essential plant nutrients. However, concerns for the effects of increased loading of heavy metals, particularly cadmium, will require improved treatment technologies, e.g., source reduction, removal from waste streams, and separation of high cadmium from low cadmium sludge with the application of the former to non-food producing sites.
- Animals exposed to cadmium produce manure which can recycle to soil, adding significant amounts of cadmium as well as valuable nutrients. Where such manures are applied repeatedly in high quantities to localized areas, high cadmium levels may result.
- Phosphatic fertilizers are produced from phosphate rocks which vary in cadmium content from less than one to over $100\,mg\,kg^{-1}$. Igneous deposits have lower cadmium contents but account for approximately 5% of world reserves.
- The development of economically feasible cadmium reduction technologies should be pursued.
- There are regional differences in the sources of phosphate rocks used in fertilizer production, in addition to varying rates of application, so that generalizations regarding cadmium input are fraught with danger.
- Phosphatic fertilizers are essential for agricultural production and in many countries, particularly in Africa, where major increases in food production are required, soils are deficient in phosphate.
- The need and demand for phosphatic fertilizers will continue to increase, and risk management for cadmium must balance the costs and benefits and the risks associated with phosphatic fertilizer use.
- The contribution of each source: atmospheric deposition, animal feeds, biosolids and phosphatic fertilizers, to total cadmium in soil and to bioavailable cadmium requires evaluation at different spatial scales.

FOOD CHAIN

The following points are important in the context of cadmium toxicity:

- Bioavailability of soil cadmium to plants (phytoavailability) is a function of both soil supply parameters and plant demand parameters, and exerts great influence on both ecological and human food chains.
- Soil supply is primarily a function of the soil cadmium concentration, and partitioning of cadmium between solid and solution phases. Partitioning is primarily governed by soil acidity, but other competing (e.g., calcium, Ca) or complexing (e.g., chlorine, Cl) ions in solution, and the type of solid phases present (e.g., clay type and content, amount of organic matter) also influence cadmium partitioning.
- The soil chemistry of cadmium is complex and affects phytoavailability and leaching.
- Movement of cadmium through soil, to plant roots or to groundwater, is an area of increased research activity. Cadmium movement is affected by the distribution between solid and aqueous phases. More accurate measurements of cadmium leaching in a variety of agricultural systems are urgently needed to determine long-term accumulation potential, both in soil and groundwater.
- Plant demand for cadmium and translocation of cadmium to edible parts are moderated by the presence of competing ions in solution (e.g., Ca, hydrogen, H, zinc, Zn). Deficiencies of zinc, in particular, may lead to high cadmium accumulation.
- Growth rates and root proliferation in soil are affected by plant nutrient status (e.g., phosphate availability), so that soil fertility also plays a role in cadmium phytoavailability.
- All plant species appear to access the same pool of soil cadmium, with no evidence of solubilization of less-available pools evident by any species to date. However, due to different root uptake and translocation, very large differences in cadmium accumulation are evident between species and between cultivars within a species. This can be exploited to develop low cadmium cultivars or those suitable for phytoremediation. Improved agricultural practices can reduce cadmium phytoavailability.
- Bioavailability of cadmium to soil microorganisms is much less well defined, but appears to be related to the dissolved cadmium concentration, although soil invertebrates may have exposure to cadmium through the soil solution, dermal contact, and ingestion of soil and food. Invertebrates vary greatly in sensitivity to cadmium. Some soil invertebrates appear tolerant;

many aquatic invertebrates are highly sensitive. The relative importance of these various pathways and the ecologic consequences have not been clearly identified.

- Soil ingestion by grazing livestock or wildlife appears to be a less important exposure pathway than ingestion of herbage. Animals act as a barrier to cadmium transfer through the food chain to humans because of their low intestinal absorption and the sequestration of cadmium in livers and kidneys, leaving muscle tissue (meat) relatively low in cadmium. As with humans, cadmium accumulates with age in animals. Unless significantly large quantities of organs from older animals are consumed, cadmium transfer through this pathway is limited.
- Although there are abundant data on total cadmium concentrations in foods, bioavailability of plant cadmium to animals or humans is not a simple function of food cadmium concentration. It is related to the form of cadmium in the food and other nutritional factors, e.g., Iron (Fe), Zn, Ca and phytate ($C_6H_{18}O_{24}P_6$). Low concentrations of iron, zinc and calcium appear to increase food cadmium bioavailability, especially in the case of rice. Identifying and predicting food cadmium bioavailability is an urgent priority.
- Direct ingestion of soil by humans may also be a significant exposure pathway in highly polluted soils, e.g., eating of soil by children. This is unlikely in agricultural food chains and is usually related to urban or industrial sources of contamination in residential areas. However, conversion of farmland to residential land (suburbanization) is proceeding rapidly, particularly near large cities in developed nations. Therefore incidental or deliberate geophagy may sometimes become important for cadmium.
- Ingestion of cadmium in drinking water was a significant pathway leading to Itai Itai disease in some areas of Japan. Industrial effluents and atmospheric deposition add cadmium to surface waters used for drinking in many parts of the world. Leaching of cadmium, while reducing plant uptake, contributes to ground water contamination. The implications vary with hydrology, aquifer features, and demand. Understanding cadmium in water(s) is of particular importance for ecological risk assessments.

CONSEQUENCES

Human Health

Cadmium is a toxic and carcinogenic element. The International Agency for Research on Cancer has identified cadmium as a known human carcinogen. Epidemiologic studies of cadmium-exposed workers show excess lung cancer. However, cancer has not yet been shown to be a risk from ingestion of cadmium at levels encountered in the environment. The main non-cancer endpoint of concern is kidney damage, particularly to the proximal tubule, but also to the glomerulus. Bone and hematologic disorders have also occurred at high level exposure. A wider range of organ toxicity has been demonstrated in animals.

Risk Assessment

Assessment of the human health consequences of environmental exposure to cadmium and the resulting policy implications should be based on the results of quantitative health risk assessment. The traditional risk assessment paradigm has four steps each of which is subject to major uncertainties.

In the hazard identification step, high level cadmium exposure has clearly caused significant kidney disease and bone weakening, represented by the Itai Itai disease in parts of Japan. Lower level exposures have caused kidney damage in other environmentally exposed populations (e.g., Cadmibel study). Proteinuria is the critical endpoint, but the critical level of proteinuria which represents a significant and unacceptable change is controversial.

The dose response relationship between cadmium exposures and proteinuria remains incompletely characterized. The usual measure of cadmium body burden, urinary cadmium (U-Cd), is itself dependent on kidney damage. The relationship is further confounded by the effects of age on both cadmium level (U-Cd usually declines after the 7th decade) and proteinuria (which normally increases in the elderly). There are associations between occupational exposures (intensity and duration), cadmium levels in urine and kidney, and biomarkers of kidney damage. Both the glomerulus and the tubule can be damaged, resulting in both high and low molecular weight proteins in the urine. In general it is the tubular effect which is considered the most sensitive, although it is likely to be the glomerular damage which is of greatest clinical significance. In the general population exposed to cadmium, proteinuria has been reported at a U-Cd of $5\,\mu g\,Cd\,g^{-1}$ creatinine, with some studies showing elevations at U-Cd levels as low as $2.5\,\mu g\,Cd\,g^{-1}$ creatinine, however criteria for defining elevation have varied among researchers.

Improving the exposure assessment requires quantifying how the relationship among intake, uptake and distribution are mediated by the interaction of several factors under a wide variety of conditions. These include zinc, iron, and calcium status (as well as current levels of these cations in the diet). Because both cadmium concentrations and bioavailability in soil and foods and nutritional status of the studied populations vary, care must be taken in generalizing from the few studies that have been conducted, mainly in Europe and Japan. Intake of cadmium from home gardens varies greatly, and may be a significant source of cadmium for some people in developed nations as it is for subsistence farmers.

The effective dose (dose to the kidney) cannot be measured directly, making risk characterization difficult. Biomarkers of exposure include cadmium in blood (relatively short half-life), U-Cd (correlated with kidney cortex cadmium, but disproportionately excreted when the kidney is damaged), as well as *in vivo* estimations of organ cadmium by neutron activation and X-ray fluorescence, which are not yet widely available or sufficiently sensitive for low level exposures. The low molecular weight proteins, called biomarkers of effect, are often quite well correlated with exposure, but the lack of a completely independent biomarker of exposure is a source of uncertainty in risk assessment.

The World Health Organization has developed a Provisional Tolerable Weekly Intake (PTWI), basing its risk assessment mainly on data from studies of the Japanese Itai Itai disease. Many assumptions and some uncertainty factors are involved which may no longer be appropriate, particularly for other populations, and which may over- or under-estimate risk. The relationship between an average level of $10\,\mu g\,Cd\,g^{-1}$ creatinine in urine and the frequently cited critical concentration of approximately $200\,\mu g\,Cd\,g^{-1}$ tissue in the kidney cortex seems to be reasonably consistent, but the relationship is not linear. The estimation of $7\,\mu g\,kg^{-1}\,week^{-1}$ (corresponding to an allowable daily intake of $1\,\mu g\,kg^{-1}\,day^{-1}$) may benefit from re-examination. Depending on the outcome, the dietary contribution from various sources (some published, some additional ones needed), can be compared to identify populations that may be very close (within an order of magnitude) of the PTWI.

Ecological Effects

Many ecotoxicologic studies have been conducted on selected species. There is wide variability in uptake, storage and effects of cadmium among most groups studied, but data, particularly on effects, are sparse, and interactions among metals need to be examined. Studies need to focus on organisms relevant to particular areas of cadmium contamination. Very few standardized indicators useful for ecotoxicology assessments exist, and they do not represent all trophic levels.

Toxic impacts on one species may be biomagnified through ecosystem food chains, and effects may include changes in the health, longevity, or reproduction of certain species, as well as alterations in the flow of energy and the cycling of matter. Therefore ecological risk assessment becomes much more complex than human health risk assessment. Many studies are carried out on the microcosm (aquarium scale), and these need to be expanded to the mesocosm (pond-scale) level. In addition, studies of terrestrial ecosystems and factors modifying the bioavailability and transfer of cadmium at every trophic level are required.

POLICY

Risk Management

A defining feature of sound risk management is stakeholders, who must live with the options and should have input into the risk process. This requires that the selection of endpoints be relevant to the population, and therefore risk management strategies to prevent a particular hazard, may differ regionally and over time. Risk management must take into account competing risks and must not introduce greater risks.

The precautionary principle (*see* Precautionary Principle, Volume 4 and 5) dictates that, in the absence of data or in the presence of uncertainty, risks should be managed at low levels until data are available indicating that less protection is warranted or acceptable.

Given that cadmium may continue to build up in the environment, and future exposures may be substantially higher than at present, and that Cd is hazardous to human health and ecosystems, it is prudent to keep cadmium levels and bioavailability at safe levels.

Economic Issues

Measures and policies to reduce the potential risks to human health from food produced on soils with different levels of accumulated cadmium may be costly. Internationally-accepted food standards and requirements will change the patterns of world trade in both food products and fertilizers. Imposing food quality criteria will require fertilizer manufacturers, farmers, marketers and consumers to modify their behavior. The costs and benefits to each stakeholder need careful consideration. Controls at the fertilizer input level may be costly to the fertilizer production industry and ultimately to farmers and food consumers, particularly in the developing world where rapidly growing populations create increased energy demand. The removal of cadmium from phosphoric acid (H_3PO_4) (decadmiation) is not cost-effective at present prices. The technical and economic conditions under which decadmiation becomes an economic option need to be established. The costs and benefits of alternative policy measures must be established in order to set socially optimal food safety levels. Their consequences for food security and international trade of less developed countries are particularly important.

CONCLUSIONS

1. Cadmium is a toxic and carcinogenic metal, nearly ubiquitous in the environment. It is hazardous to humans and ecosystems in excessive amounts.
2. Inputs are mainly from atmospheric deposition, application of biosolids, use of phosphate fertilizer, and

from effluents from cadmium-using and recycling industries.

3. These inputs to the environment can be subject to control methods which vary in their economic and social costs.
4. There are significant data gaps related to bioavailability and food chain transfers, particularly under tropical conditions.
5. Caution is needed in generalizing exposure estimates from the existing epidemiologic studies, because of substantial differences between occupational exposure (primarily inhalation) and community exposure (primarily ingestion), as well as between cultures with different diets and perhaps susceptibilities.
6. The most sensitive human health endpoint of concern for human food chain exposure is damage to the proximal tubule of the kidney with resulting proteinuria.
7. The significance of low-level proteinuria and its relationship to exposure duration and levels is controversial and cannot be resolved with the existing epidemiologic data. This limitation precludes recommending specific cadmium levels for the environment.
8. Identifying the susceptible subsets of the population is important, and many factors influencing susceptibility remain to be identified and quantified.
9. There remain significant data gaps in the area of ecological risk assessment, particularly at the ecosystem (rather than single species) level.
10. There is a need to prioritize risk reduction strategies for the major cadmium sources.
11. In addition to the uncertainties concerning food chain and biomedical issues, there remain uncertainties regarding the benefits, costs and potential risks associated with various cadmium management scenarios.
12. The growing populations imposing increasing energy demands and the limited arable land (much with low natural fertility) of developing countries in tropical regions requires special attention with regard to risk balancing.
13. There is an urgent need to support further research on the topics identified above as having high priority.

BACKGROUND INFORMATION

This contribution is based on the results of a Scientific Committee on Problems of the Environment (SCOPE) workshop *Environmental Cadmium in the Food Chain: Sources, Pathways and Risks*, held at the Belgian Academy of Sciences, Brussels on 13 16th September, 2000, which in turn built on prior conferences, including a meeting of the International Agency for Research on Cancer (Gargnano, Italy, 1991), a Workshop on cadmium of the Organization for Economic Cooperation and Development (Saltsjobaden, Sweden, 1995), and a symposium on cadmium (Berkeley, USA, 1997). The first meeting emphasized health effects and the last two soil plant relationships. Each stressed the importance of reducing risks to human health and the environment from cadmium.

The workshop included 32 technical papers in five plenary sessions, two summary reports of prior meetings, eight working group reports, and a follow-up meeting to develop this consensus summary. Further details and recommendations are provided in the Workshop Working Group Reports, which are posted on the SCOPE website (2001).

Fisheries: Effects of Climate Change on the Life Cycles of Salmon

Ian A Fleming[1,2] and

Arne J Jensen[1]

[1]*Norwegian Institute for Nature Research, Trondheim, Norway*

[2]*Coastal Oregon Marine Experimental Station, Newport, OR, USA*

Changes in climate are likely to impact water temperature, quantity and quality and thus alter the biological composition, production and function of aquatic environments. Understanding the responses of aquatic life, such as fish, to these changes represents a fundamental ecological challenge. Temperature affects all vital processes of cold-blooded aquatic organisms, including activity, feeding, growth and reproduction. Thus, it is widely believed that climate warming will affect the distributions of marine and freshwater species, resulting in a general shift polewards to reflect their thermal preferences. Moreover, the composition and relative abundance of species in local communities will shift towards those of warmer temperatures. It is also predicted that these effects may be more pronounced towards the poles where warming is expected to be greater than in the tropics. Evidence is growing that such changes are occurring in both marine and freshwater ecosystems in response to the warming of aquatic environments in recent decades. Climate change will not only affect aquatic environments through the direct effects of temperature, but also through other environmental changes coincident with, or driven by, the changes in temperature. Ocean currents are predicted to change and with them so will circulation patterns and regions of nutrient upwelling that affect water quality and biological productivity. For example, the Eastern Pacific Ocean, which has undergone warming in recent decades, has experienced a concurrent decline in productivity, particularly in the near-surface zone. The cause, however, remains poorly understood, but the implications are far reaching for the ecological community. Climate change will also alter annual and seasonal precipitation patterns and increase variability within and among years, which are expected to have profound effects on freshwater environments, affecting lake levels and stream flows. Moreover, if changes in water quantity occur with changes in water temperature, then changes in water quality will likely follow, owing to changes in concentrations of ions, dissolved gases, and organic materials. Thus, the effects of climate change on aquatic environments, both marine and freshwater, are expected to be multifaceted.

SALMON AS AN INDICATOR

Fishes, such as salmon, which spend their lives both in freshwater and marine environments (i.e., diadromous; Figure 1) are ideal for the study of responses to climate change and may prove to be good biological indicators of it. Their life cycle, which takes them from freshwater through estuarine and out into open ocean habitats and then back again, exposes salmon to a diversity of potential effects resulting from climate change. The typical life cycle of anadromous salmon (*Oncorhynchus* and *Salmo* spp.) begins with the spawning of eggs into nests constructed in the gravel of freshwater rivers or streams during the fall (Figure 1). The eggs incubate through the winter and hatch in the spring, with the juveniles emerging from the gravel shortly thereafter. The juveniles remain in freshwater streams, rivers and/or lakes for as little as a couple of months or up to several years (five) before migrating through estuaries and out into the ocean. It is in the ocean where the vast majority of the salmon's growth occurs over a period ranging from a few months up to several years (four). During this oceanic period, salmon appear to be almost continuous travelers and may migrate distances in excess of 5000 km away from the oceanic outlet of their natal river. They then return to their natal river to breed and may migrate up to 4000 km in fresh water to reach their spawning grounds. Accurate homing to the natal river to breed facilitates the evolution of population-specific traits and the intra-specific variation that so characterizes salmon species.

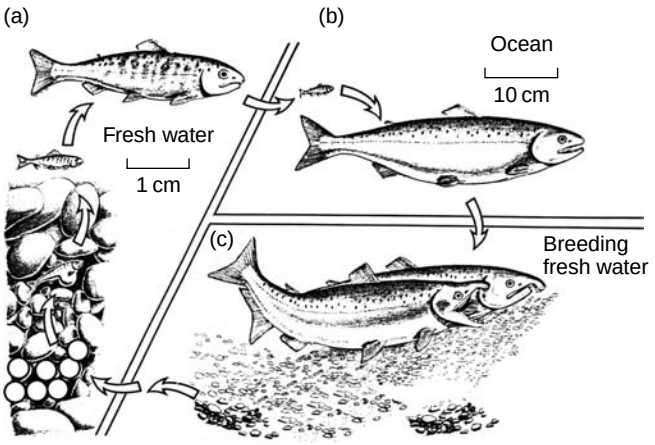

Figure 1 A generalized life cycle of anadromous salmon, involving (a) egg incubation and juvenile rearing in fresh water followed by (b) migration to the ocean for sub-adult growth and then (c) the return to fresh water for breeding

Global warming is predicted to affect freshwater before it affects marine habitats because of the relatively rapid effects of changes in runoff and precipitation on freshwater systems, and the buffering capacity of the oceans. Moreover, rivers and streams are likely to be among the most sensitive aquatic environments to warming because of their small volumes and sensitivity to changes in flow discharge. Thus salmon, with their early and adult life history stages occurring in these environments, will be exposed early on to such direct effects of climate change. In addition, it is generally thought that temperate species, such as salmon, will be more susceptible because warming is predicted to be greater at higher than lower latitudes. Salmon will also be subject to the indirect effects of climate change, such as changes in ocean currents, wind patterns and timing of river flows, that affect the productivity and availability of food, the costs of migration and mortality.

Generally, it is difficult to predict the responses of aquatic animals to climate change, partly because of lack of information about their environmental requirements and the dynamics of their life histories. Salmon, however, have been well studied and quantitative models exist for such things as growth, feeding, egg incubation, thermal tolerance and life history. In addition, a number of long time-series on salmon populations exist by which the responses to climate change may be identified. Finally, the large amount of among-population variation within salmon makes them well suited to study, because the first response of organisms to changing climate will involve changes at this level.

RESPONSES OF SALMON TO CLIMATE CHANGE

Climatic warming is likely to affect salmon species negatively, particularly those populations that rely extensively on freshwater habitats for juvenile rearing. They are likely to face altered water temperatures and precipitation related changes in flow regimes. It is predicted that there would be major alternations in river hydrology resulting from earlier snow melt and increases in the elevations at which freezing occurs. As the flows of many salmon rivers are dominated by snowmelt, summer runoff may decrease and winter runoff may increase.

Climate change may impact salmon at a variety of life stages, beginning at egg incubation (Figure 2). Changes in water temperatures and river flows during this life stage may cause sub-optimal juvenile emergence from the gravel nests and result in increased egg and early juvenile mortality. Egg development is largely temperature dependent, as is the period following hatching when juveniles remain in the gravel for several weeks surviving on the nutrients in their yolk sacs before beginning exogenous feeding and emerging. The timing of emergence from the gravel has likely evolved in response to selection for a presumably optimal time for survival (e.g., temperature and flow), food availability and competitive advantages. If winter temperatures increase following climate change, egg incubation will be shortened and result in earlier juvenile emergence

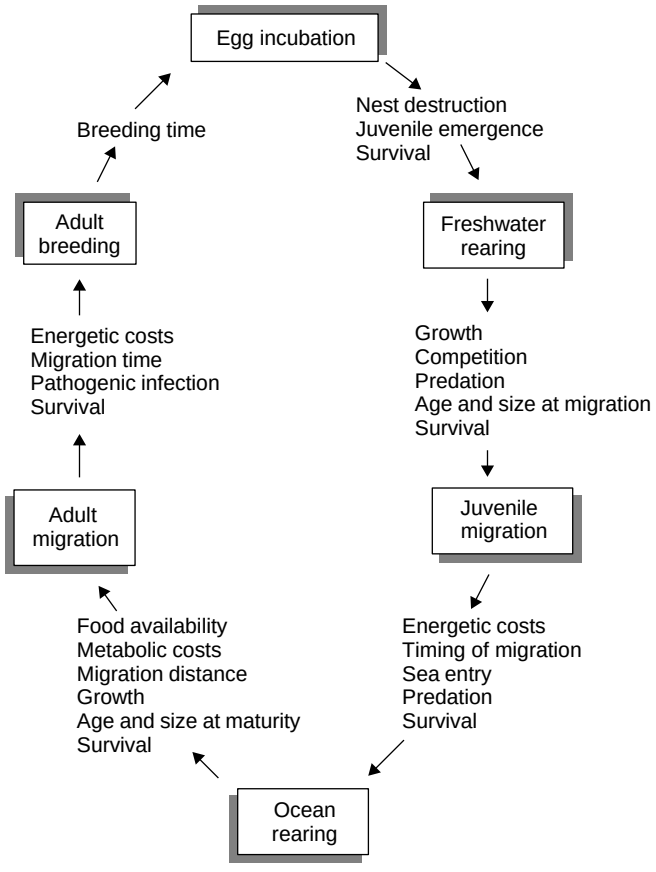

Figure 2 Potential impacts of climate change at various life stages of salmon

from the gravel, in the future. Such a shift away from the optimal timing for juvenile emergence is likely to result in increased mortality. Moreover, if climate change results in increased winter flows, as many models predict, gravel shifts caused by flooding may become more frequent and larger, increasing the susceptibility of incubating eggs to destruction. In addition, increased flows may occur during emergence, when the juveniles are highly susceptible to displacement.

The subsequent growth and survival of the juveniles in fresh water will be affected directly by temperature and flow regimes, and indirectly through changes in the aquatic community in response to the altered hydrology. Each salmon species has characteristic upper (usually below 30 °C) and lower (freezing) temperature limits for survival. Within these limits, there is an optimum temperature range over which feeding and growth occurs (e.g., 6 22.5 °C for Atlantic salmon), but this range declines as the availability of food declines. The effects of climate warming on growth of juvenile salmonids can thus be expected to differ with latitude.

At the southern edge of their distribution area, salmon growth may be retarded and mortality higher because of expanded periods with unfavorably high temperatures. This may be further compounded by the expected reductions in flow and thus habitat during summer months. Generally, stream flow is positively related to habitat space for, and thus abundance of stream fishes. Increased water temperatures may also alter the aquatic community structure, both in terms of the forage base for juvenile salmon and the competitor and predator communities. Expansion of the ranges of more southerly, warmer water communities is expected. Such potentially deleterious effects on growth may, in turn, influence over-winter survival and subsequent marine survival, both of which are size related.

In northern areas, on the other hand, growth rate will increase because of more favorable temperatures during summer and a longer growing season. However, droughts may be more frequent during summer than today, resulting in reduced habitat and food availability, and thus retarded growth. On the whole, however, freshwater growth is expected to be better and the age of migration to the ocean (smolting), which is growth related, lower than today. Moreover, because production of salmon smolts is inversely related to age of smolting due to annual freshwater mortality rates of 40 60%, the smolt production is expected to increase in northern rivers. Thus, losses in production of juvenile salmon in the south may well be overridden, at least initially, by gains in the north.

The spring photoperiod is considered the major environmental cue initiating the transformation from freshwater juvenile to seaward migrating smolt, whereas various river-specific stimuli (e.g., water temperature, water flow, and lunar cycle) regulate the timing of the seaward migration. Such river-specific stimuli likely reflect local adaptations that have evolved to insure an optimal timing of smolt migration in terms of survival and subsequent growth. For example, descending smolts are subject to heavy mortality from fish and birds in the river and estuary. To avoid such predation, smolts migrate down river in schools. If climate change results in reduced spring flows, as is predicted for many temperate rivers, the smolt run may be more dispersed over time and schools smaller in size, resulting in increased exposure to predation. Moreover, the energetic costs of migration may be higher and time taken to descend longer. Changes in river temperatures and flow regimes may also lead to sub-optimal timing of entry into the sea. Timing of sea entry is critical for the early sea survival of smolts because of physiological stress, metabolic costs, food availability and predation, all of which are influenced by sea temperatures.

Once in the ocean, salmon are likely to face further effects of climate change including altered sea surface temperatures, currents and areas of nutrient upwelling, all of which directly or indirectly affect their lives. It has been predicted that modest rises in sea surface temperatures, in line with predictions of global warming over the next half-century, could cause salmon to disappear from much of the North Pacific Ocean. During November March, for instance, sockeye salmon are only found in regions where the sea surface temperature is below 7 °C and thus show remarkably low thermal limits which excludes vast areas of the North Pacific that are otherwise potentially habitable. It is speculated that this is driven by interactions between water temperature and metabolic rate when food supplies are low. The salmon may be avoiding warmer water because food supplies are insufficient to maintain high metabolic rates, which increase exponentially with temperature in cold-blooded animals such as fish. In addition to a reduction in their habitat, a northern shift in its distribution will force salmon to travel farther to reach their breeding rivers, resulting in smaller fish with fewer eggs.

In the Atlantic, where salmon survival, particularly that of out-migrating juveniles, appears related to the areal extent of 8 10 °C water during spring, the situation may be more complicated. Sea surface temperatures may interact with changing currents to either decrease or increase area of the 8 10 °C water during spring and thus, salmon survival. Warmer sea surface temperatures in the Atlantic may also lead to a northward expansion of the range of salmon, as apparently occurred during 1919 1938 when a strong inflow of warm Atlantic water into the Kara Sea, Northern Russia, led to the eastward expansion of salmon.

Warmer sea surface temperatures are also likely to interact with currents to alter the marine communities exploited by salmon, reducing food availability (zooplankton biomass). It has been speculated that this, coupled with higher metabolic costs in warmer water, will lead to smaller

salmon, a prediction that is consistent with evidence that climate variation over the North Pacific Ocean is responsible for long-term (1925 1993) trends in the body size of sockeye salmon.

Upon return to fresh water during their breeding migration, adult salmon are likely to encounter increased water temperatures and decreased river flows associated with climate warming that may cause additional prebreeding mortality and reduced egg deposition. Increased water temperatures influence temperature-related metabolic processes, with energy expenditure during migration increasing exponentially with temperature. Moreover, because of a positive relation between temperature and pathogenic infection rate in salmonids for several bacterial pathogens, increased temperatures will likely increase the susceptibility of breeders to pathogens and parasites. Reduced water flows, in addition to affecting water temperatures, will also influence the ease of migration because it is a primary determinant of upstream fish passage. In general, lower flows create lower velocity conditions that enhance upstream fish passage. Many rivers, however, have obstacles (e.g., falls, barriers) that can only be passed during higher flow conditions. Thus delays in river ascent may occur, increasing the energetic expense for the adults, which do not feed during the breeding migration. Such low flows are also believed to select against large adult body size, which could result in reduced salmon size in many rivers.

Finally, breeding time in salmonid fishes appears adapted to present day thermal and flow regimes in such a way that conditions are favorable for breeding, egg incubation and juvenile emergence and subsequent feeding. Thus, climatic induced changes in thermal and flow regimes are likely to have deleterious consequences for one or more of these life history events that are intimately linked to breeding time.

Climate change is thus likely to impact the life cycle of salmon at a variety of stages (Figure 2). Salmon do have the ability to respond immediately to warming events, such as an El Nino, by altering migration patterns. However, this response is often either inappropriate, or insufficient to compensate for strong negative effects on growth and survival. Thus, while the response of salmon to climate change will, at least initially, involve environmentally mediated changes (i.e., phenotypic plasticity) in life history, it will likely require longer-term genetic change as well. The speed and ability of the life history to respond (through plasticity and genetic change) will be important in determining the extent to which salmon populations become compromised.

Fisheries: Minamata Disease

Akira Kudo
Kyoto University, Japan

In the 1950s, an environmental disaster brought human misery to a sleepy shing village facing a small inlet called Minamata Bay, in Southwestern Japan. More than 100 people living around the bay died and many thousands more were permanently paralyzed after eating sh contaminated with mercury (methyl mercury, $CH_3\ Hg^+$), an effect known today as Minamata disease.

The Minamata disaster was the first known case of multiple deaths as a result of the natural bioaccumulation of a toxic material in industrial wastewater. It was different from other causes in which deaths followed direct consumption of contaminated water or food.

Minamata Bay s fatal mercury (most of which was in inorganic form, methyl mercury/$CH_3\ Hg^+$) was discharged from a nearby chemical factory in the 1930s 1960s, settling and accumulating in bottom sediments, at concentrations of up to 600 ppm. In 1976, the local Kumamoto prefecture estimated that 150 tonnes had been released into the 3 km^2 bay, where it remained and was chemically transformed naturally into more toxic (more than 1000 times for humans) organic mercury.

In the aquatic environment, mercury maintains an equilibrium between inorganic and organic chemical forms (Kudo *et al.*, 1977). In most cases, the ratio of organic to total mercury ranges from 0.5 to 5% and the rest (95 99.5%) is inorganic.

The ratio of mercury from the chemical factory in Minamata was no exception and measured as 0.5 1.5% methyl mercury (Irukayama, 1966). In other words, methylated mercury was constantly produced (transformed) at the bottom of Minamata Bay from large amount of inorganic mercury discharged from the factory. The production rate reached an equilibrium due to the dilution by tidal sea water and the natural destruction of methyl mercury into the inorganic form. This fact contradicts the still prevalent assumption by many Japanese, including the court decisions, that all methyl mercury was discharged directly from the chemical factory.

The reason why so many human casualties occurred around the Minamata Bay while many aquatic systems in the Western world contaminated by similar level of mercury have not resulted in any human loss lies in the unique aspects of Japanese culture. In Japan, a) fish is heavily consumed as the major protein source and b) harmony in the traditionally social structure is more important than the discovery of new scientific facts. Bureaucrats in Japan will usually take no action until a slowly-evolving consensus has been reached. Furthermore, there is a built-in-system, which makes each bureaucrat s responsibilities extremely vague and diluted.

The professors in the major Japanese universities are part of the bureaucratic system. Few resources were allocated for scientific investigation of the cause of Minamata disease, which proceeded slowly and was limited. During this fact-finding period, most of the casualties occurred. Surprisingly, the cause of Minamata disease was not found by analyzing mercury in the bottom sediments of the bay, but by a unique symptom of mercury poisoning recognized in clinical patients. In other words, the most experienced analytical scientists with modern equipment in Japan were not mobilized to detect Minamata disease. Furthermore, when the chemical company ceased to use mercury in 1968, most research on Minamata disease and on the mercury in the surrounding environment in Japan virtually ceased (see Figures 1 and 2).

The large amount of mercury discharged into a natural system, Minamata Bay, provides a rare opportunity to trace the mercury behavior in the aquatic system. At the same time both the local and central governments have held to their positions since 1960s that none of the mercury from the bottom of the bay has ever moved, escaped or been dispersed to the outside.

A group of scientists measured the dispersal of the mercury from the bay into the surrounding water body of the Yatsushiro Sea after 1975. What really happened to the mercury deposited in the bay prior to 1968? Did it escape into the Yatsushiro Sea? If so, what is the increase of mercury in the surface sediments of the sea? Over 25 years of investigations have produced answers on mercury behavior in the natural environment, which throw doubts on official statements.

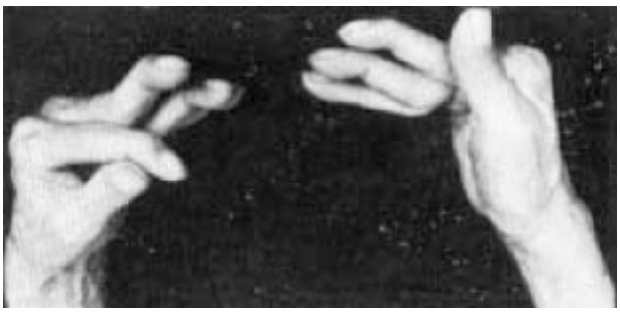

Figure 1 Fingers deformed by Minamata disease. (Photo from Dr M Harada, Kumamoto University)

Figure 2 Decontamination project removing contaminated bottom sediment at Minamata Bay. (Photo from Kumamoto Prefecture)

During the last 25 years, surface sediments have been collected from 24 fixed sampling stations to a depth of 4.0 cm in the Yatsusiro Sea. Researchers have found that the mercury content of the samples was not a cause for concern and that the concentrations outside the bay were below the acutely toxic level. At the same time the investigators spotted a trend in mercury behavior in the 633 km^2 Sea (Kudo and Miyahara, 2000).

Between 1975 and 1984 mercury concentrations gradually increased, with sampling stations close to Minamata Bay showing the greatest rise, from 0.62 ppm in 1975, to 10.3 ppm in 1984. At another, more remote, station, concentrations rose slightly. The pattern was interrupted in 1982, an exceptional year when 400 mm of rain fell in three hours, a 200-year event. Millions of tonnes of clean soils were washed from surrounding mountain slopes to cover the sediments in the Yatsushiro Sea.

Three years after this storm, the government initiated a decontamination project. Mercury concentrations at one sampling station near the bay dropped from 10.5 to 1.56 ppm from 1985 to 1990 and decreased further to a background level of 0.3 ppm in 1997.

The Japanese government eventually took responsible action against mercury pollution in the bay, but it was too slow to act. The decontamination project costing US$500 million and the first such effort in the World, will clean up the bay and protect the people around Yatsushiro Sea for many years to come.

Fisheries: Pacific Coast Salmon

David Welch

Pacific Biological Station, Nanaimo, Canada

The eight species of Paci c salmon (genus Oncorhynchus) form one of the most valuable sheries resources in the world, and have high value to the peoples of the Paci c Rim as an indicator of the health of the natural ecosystem. Paci c salmon are particularly vulnerable to climate change because their complex life histories involve extended periods of life in both the freshwater and marine ecosystem, exposing them to climate disruptions in both habitats.

Climatic changes that disrupt the life cycle of Paci c salmon and reduce the chance of successful breeding are especially serious, because in most species, adults die after breeding. This makes the persistence of populations dependent on successful completion of the life cycle to a much greater degree than in animals where adults have the opportunity to reproduce more than once. As a result, once sexual maturation starts and salmon begin their long migration back through the sea and up the rivers, events that disrupt breeding success leave no chance for the animals to leave and return to breed the next year. In addition, substantial differences in behavior between populations, such as in the timing of egg development, hatching, and spawning, as well as strong delity to the spawning grounds, are believed to be inherited and the result of strong selection to their local environment. Such characteristics may be particularly vulnerable to disruption by climate change.

All species of Pacific salmon begin life as fertilized eggs laid in nests dug out of the gravel or cobble bottoms of lakes and rivers. The embryos then develop over the winter before hatching. Following hatching, the fry emerge from the gravel in the spring. In pink and chum salmon, the fry quickly leave freshwater and enter the ocean. In the remainder of the species, the young salmon make much more extensive use of the freshwater habitat (rivers and lakes) for one or more years before migrating to the sea.

After entering the ocean, a period of time may be spent in estuaries or near-shore habitats where adaptation to the marine environment is completed and rapid growth begins. Most salmon then begin a rapid and highly directed northwards migration along the narrow continental shelf, where most eventually leave the coastal zone and remain in the open ocean for a period of several years. As sexual maturation begins, salmon begin directed homing migrations over long distances in both the ocean and freshwater. Much less is known of the marine phase of the life history than the freshwater phase, but evidence accumulated over the past decade suggests that changes in ocean survival have been at least as serious as changes in freshwater survival.

Most growth and approximately half of the mortality occurs in the ocean. As a result, climatic disruptions that happen at any point in the life history can result in severe impacts on survival rates. Freshwater migrations are affected by changes in water temperature, and rate and timing of river flow. Climate change projections generally indicate that winters will be warmer and wetter in future, while summers will be warmer and perhaps drier. With more precipitation falling as rain rather than snow, the spring run-off is expected to occur earlier and be more intense in future, while river flows in summer will probably be warmer and less rapid, providing less moderation of summer temperature extremes. Young fish migrating to sea may be affected by changed timing of river flows, or mismatch with peaks in ocean production. Adult salmon returning to breed may experience strong river flows and high water temperatures that drain their energy reserves to the point that they are unable to reach the spawning grounds. The unusual warming experienced in the 1990s saw much higher mortality of adult salmon returning to many parts of British Columbia s Fraser River. This was apparently a result of high temperature and stream flows increasing the energy demands on migrating adults, while reduced growth at sea resulted in them returning at smaller sizes and with reduced energy reserves than in the past.

In the North Pacific, elevated temperatures may ultimately reduce salmon populations by limiting their ocean distribution. All species of Pacific salmon sharply avoid warmer temperatures at sea, effectively limiting them to a substantially smaller area of the open Pacific Ocean that they could otherwise occupy. Global warming models project temperature increases that could exclude several species of salmon from the Pacific Ocean within 50 years at expected rates of greenhouse gas increase (see Figure 1). Increasing temperature may also change the structure of the ocean through warming of the surface layer. Warming will increase the temperature contrast with the deep ocean, and may reduce mixing and restrict the input of essential nutrients necessary to fuel the food chain. Such an effect has already been observed in the 1990s, with the thinning of the surface layer resulting in a switch to a nitrate-depleted ecosystem in the Gulf of Alaska for the first time on record.

Several lines of evidence suggest that salmon are strongly adapted to the climate of the relatively recent past. As concentrations of greenhouse gases increase to levels not seen for hundreds of thousands of years, current adaptations may not serve salmon as well in the future. Many critical aspects of the life cycle are completed during brief time periods (e.g., timing of egg hatch, ocean entry for young salmon, breeding of adults). It is thought that evolutionary forces were strongly selective for individuals with specific characteristics appropriate for each population, and that animals deviating from these characteristics did not survive to pass on different behaviors.

Climate change is unlikely to be favorable for most salmon populations, particularly at the southern end of their range, where human populations are high and the value placed on persistence of salmon is greatest. Climate disruption is likely to exacerbate conflicts with other resource users. Water draw-down to support agriculture, and more restrictive land-use regulations on forestry or urban development to protect salmon, brings these competing resource sectors into sharp conflict as Pacific salmon populations become less productive. Hydroelectric dams one of the few energy sources that do not involve generation of greenhouse gases have also been blamed for affecting salmon populations by changing the natural flow of rivers and affecting the survival of both young and mature salmon migrating past the dams. In addition, many fisheries have either explicit legal entitlements (such as treaty rights

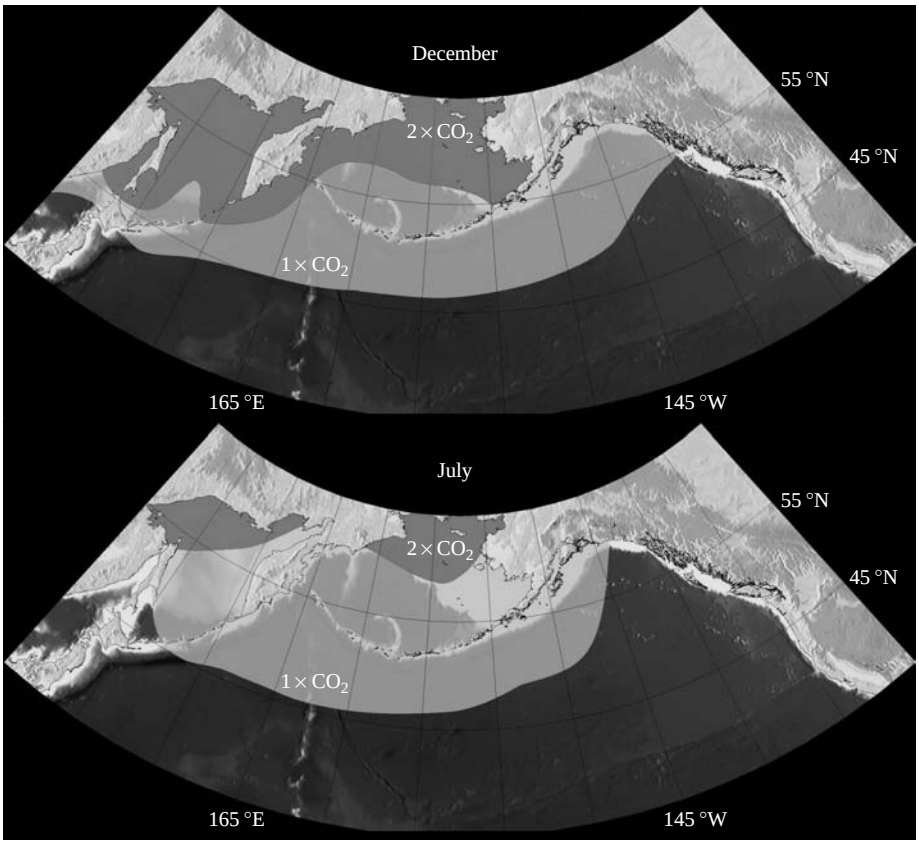

Figure 1 Current ocean distribution of sockeye salmon ($1 \times CO_2$) and projected future distribution if greenhouse gas concentrations double ($2 \times CO_2$). The lines enclose the area of the North Pacific that research shows salmon feed in, and the region of the ocean that may have similar temperatures in future. (Reproduced from Welch *et al.*, 1998)

granted to native fishermen) or implicit claims to the salmon resource based on past access.

Despite these concerns, changes in climate will not be uniformly bad for Pacific salmon. Continued warming, for example, will moderate the harsher climates in northern regions, likely improving conditions for salmon. A few sexually mature Pacific salmon have been reported from the Canadian high arctic in recent years, suggesting that the range of salmon is expanding to the north as climate has warmed. The productivity of many Alaskan salmon populations has also increased over the last few decades as salmon populations in southern regions have fallen. However, it is unlikely that the increased economic gain from the salmon catches in northern regions has outweighed the economic costs of trying to maintain salmon populations in southern regions. At least in North America, recent climate warming has had decidedly mixed effects, and the increasing disparity has resulted in bitter argument over salmon conservation.

Fisheries: Pollution and Habitat Degradation in Tropical Asian Rivers

David Dudgeon
The University of Hong Kong, Hong Kong

Anthropogenic in uences threaten the biodiversity of rivers and their associated wetlands at global, regional and local scales, and will impair or signi cantly reduce ecosystem services. Threats to these habitats can be categorised as follows:

1. *Flow modi cation or regulation (impoundment by dams, water extraction for irrigation, etc.);*
2. *Pollution;*
3. *Destruction of instream and riparian habitat (by deforestation and drainage-basin alteration);*
4. *Over-harvesting (mainly of shes);*
5. *Global climate change.*

Freshwater shes, especially those in large tropical rivers, are relatively vulnerable to extinction, and around 20% of the global total is endangered or extinct. Asian river shes are affected by all categories of threat listed above. Deforestation has occurred or is ongoing throughout much of tropical Asia; pollution is ubiquitous and subject to little effective control; and, dam building changes patterns of ow and inundation, blocks migration routes, and fragments populations. Native sh communities will be in uenced also by the spread of exotic species. We lack unequivocal data on the magnitude of their effects, but such invasions are unlikely to be positive. Projected changes in global climate can be expected to interact with anthropogenic threats, especially in rivers where the magnitude and timing of peak and minimum ows may be altered. The effects of such synergy are dif cult to predict, in part because the relative intensity of each threat varies among rivers. This constrains our ability to protect riverine environments. A particular concern is the link between rivers and their oodplains, mediated by the annual cycle of ooding caused by monsoonal rains. Most sheries production along tropical Asian rivers depends on oodplain inundation. Where this is not restricted, yields are high. The lower Mekong Basin, for example, generates an annual catch of 500 000 t, providing around half the protein intake of human inhabitants in that region. In Bangladesh, where oodplains and the Ganges- Brahmaputra Delta occupy about 80% of the land area, ve million people depend on shing for their livelihood. The annual harvest can reach 725 000 t. Fisheries like this are threatened by engineering works intended to mitigate ood damage and prevent river erosion of agricultural land. As seasonally ooded areas diminish, so too does the sh production, which depends upon these areas. Pollution and over shing are signi cant sources of concern also. This article describes the ecological features that make Asian river shes particularly vulnerable to environmental degradation, delineates the present trajectories of change (plus the possible effects of climate alteration on river ows), and sets out the consequences of impact. The prognosis is grim. If current trends continue, sh biodiversity will decline throughout the region.

ECOLOGICAL CONTEXT

Approximately 300 genera of freshwater fishes occur in tropical Asia (for details, see Kottelat, 1989). The family composition of this rich fauna is substantially different from the Neotropics and Africa. Species richness within rivers is high: over 500 species occur in the Mekong River (ranking third in the world for fish diversity after the Amazon and Zaıre); the Kapuas River (Borneo) supports 290 species; the Zhujiang (Pearl River; southern China) has 262; the Chao Phraya (Thailand), 222; the Salween River (Thailand), 150; and, the Mahakam River (Borneo), 147. Nevertheless, inventories of the Asian fish fauna are far from complete. Few countries have made systematic assessments of biodiversity, and published inventories are sometimes based on dated literature or old museum collections instead of recent surveys. One consequence is a critical shortage of information about the conservation status of Asian freshwater fishes, even in countries where species lists are fairly complete. Thus extinctions may not be evident until long after they have occurred.

What is the ecological backdrop for fish biodiversity in tropical Asian rivers? Some of the greatest rivers in the world (ranked by order of discharge) are located within the region: the Chang Jiang (Yangtze River), Brahmaputra, Ganges, Irrawaddy, Zhujiang, Mekong and Indus. Natural lakes, apart from those associated with river floodplains, are of relatively minor importance, and are far exceeded by the extent of freshwater swamp. The ecology of tropical Asian rivers has been reviewed by Dudgeon (1999, 2000 and references therein) who emphasizes the importance of discharge seasonality on the biota and land water interactions. The predominant influence of monsoons generates a characteristic pattern (typified by the Mekong, Figure 1) whereby predictable periods of drought and water scarcity during the dry season alternate with intervals of increased

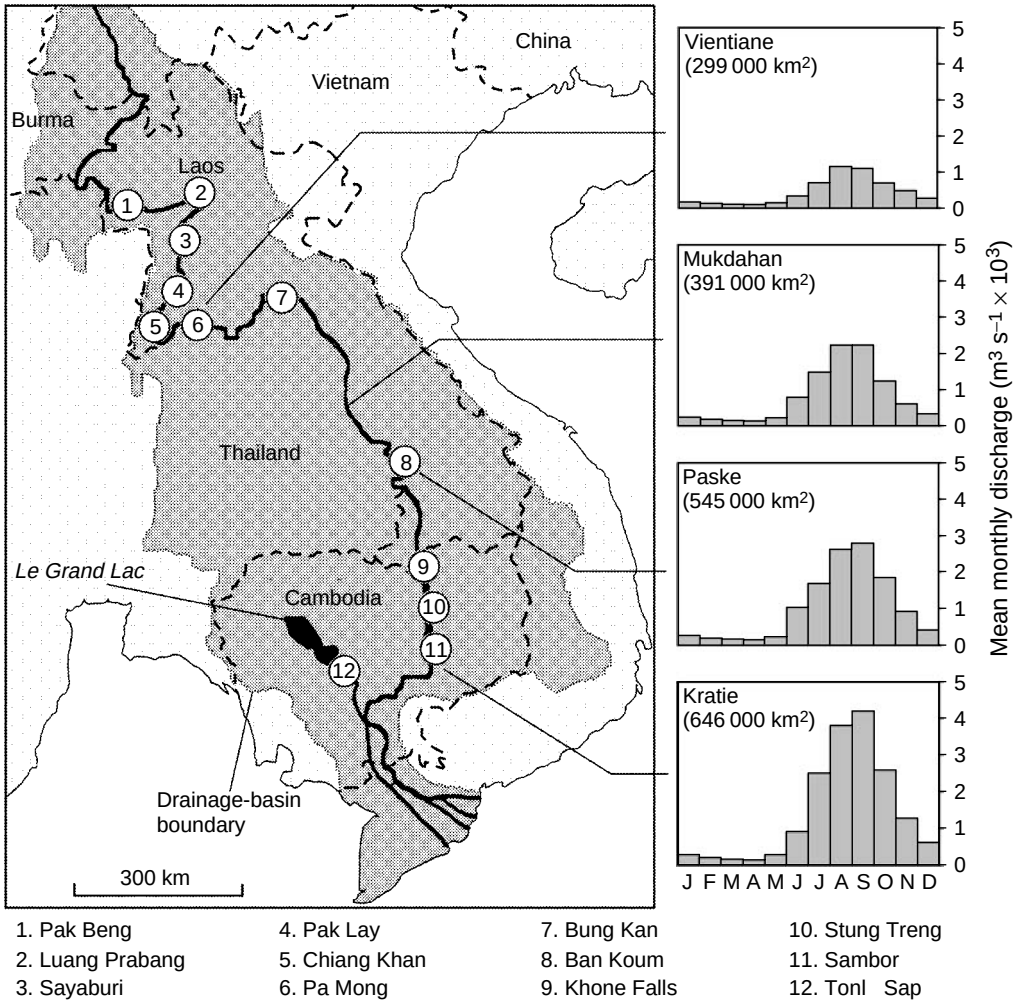

Figure 1 Locations of proposed hydropower projects along the Mekong mainstream in Laos, Thailand, and Cambodia. River discharge at four stations and the drainage basin area of each station are shown also. (Data from van der Leeden, 1975 and Roberts, 1995)

discharge, spates and flood-plain inundation during the wet season. One result is alternating periods of resource scarcity (during the dry season) and resource glut (during the wet season) for most fishes. The monsoon drives flood pulses (i.e., the predictable advance and retraction of water over the floodplain), and fish life histories (which often involve migrations) are timed to exploit land water interactions and energy inputs that occur during the inundation phase. For this reason, much of the fisheries yield from large rivers derives from floodplain habitats (Welcomme, 1976).

The Mekong is a good example of the interaction between fish ecology and discharge. That river s major floodplain lake Le Grand Lac of Cambodia (Figure 1) receives water from the Mekong (via the Tonlé Sap River) during the wet season, but water drains from it in the drier months. The lake fluctuates greatly in extent and depth. From a minimum of around 2500 km^2, the lake may swell to cover 15 000 km^2, inundating tracts of forest. Fish enter the flooded area to feed and breed, and this seasonal inundation sustains the lake fishery. Mekong fishes undertake upstream breeding migrations during the wet season as water levels rise; downstream migrations occur when levels fall during the dry season. The timing of fish migrations differs somewhat according to species and among different parts of the Mekong Basin, but this complex situation is amenable to generalization (Welcomme, 1979). Planktivorous or piscivorous pelagic fishes (whitefishes) cover a greater distance when migrating than bottom-dwelling species (blackfishes). The latter feed on benthic organisms, and make shorter, lateral movements between the main channel and floodplain or inundated forest. The two groups differ with respect to breeding habits: many blackfishes are multibrooded and practice parental care (mouthbrooding, bubble-nest building); they may have accessory breathing organs and can tolerate deoxygenation of stagnant floodplain waters. Whitefishes avoid severe conditions by long-distance migration, and are egg scatterers. Typically, they breed only once per season. An intermediate, relatively species-poor assemblage (greyfishes) have both migratory and static/territorial behavioural components, enabling them to respond facultatively to changing flow conditions. They are generalists, and may thrive where the natural flood regime has been modified.

The characteristic situation in Asian rivers involves fishes using various habitats at different times. Some of these habitats are inundated for part of the year only. Fish must therefore range throughout the river system in response to food availability. Whatever the distance covered, most species depend upon the floodplain for food and breeding sites and are subject to vagaries in the intensity of the monsoon. Thus in some years there will be extensive flooding and relatively high fish production. In years when a smaller area is inundated, production will be lower. While there is some noise in the system introduced by inter-year variation in flood peaks, it is evident that the flood-pulse is not a disturbance in the ecosystem (although human inhabitants of low-lying lands may view it as such). Instead, significant departures from the typical pattern of seasonal flow fluctuation can be regarded as a disturbance. This sets the scene for conflict between the needs of humans and fishes. The engineering response to flow seasonality is to capture and store water during flood times for use during the dry period, the benefits being amelioration of peak discharge (i.e., flood prevention) and a predictable water supply during the rest of the year. In effect, natural flow variability to which fishes are adapted and upon which they depend is smoothed out. This averaging of fluctuating flows is significant because ecological responses to environmental change are usually non-linear. Fish breeding migrations, for example, may not begin until flows have passed a critical threshold; thus a 25% increase in discharge may fail to initiate any population response.

DEFORESTATION AND DRAINAGE-BASIN DEGRADATION

While fishes in tropical Asian rivers are adapted to seasonal flow fluctuations, natural discharge regimes do not always pertain in unregulated rivers. The consequences of drainage-basin misuse and deforestation are evident throughout the region, including increased runoff, sedimentation and flash floods (Dudgeon, 1999 and references therein). In China, for example, devastating floods along the Chang Jiang in 1998 (and preceding years) focused attention on the link between catchment conditions and runoff. Government blamed the floods on years of uncontrolled logging in upland catchments. Similar consequences of drainage-basin degradation led to a logging ban in Thailand after devastating floods in 1988 claimed several hundred lives.

The loss of forest cover in tropical Asia (estimates range from 0.9 2.1% pa, but local variation is substantial) has important implications for river conservation since a significant proportion of the rich fish fauna of the region exploits inundated forest where fruit and terrestrial insects may be significant food sources. For example, forest clearance around Le Grand Lac has led to declining fish catches through a combination of reduced food, erosion and siltation. Silting causes excessive turbidity as particles are resuspended by waves in the increasingly shallow water. This limits primary production, and results in lower fish populations. Forest clearance also threatens an assortment of specialised Southeast Asian fishes confined to soft, acidic, blackwater streams which drain peat swamps. These habitats are favoured sites for timber extraction. Many blackwater fishes are severely threatened, and will become extinct (as has occurred already in parts of Malaysia and Indonesia) if logging and degradation of their habitats continues.

Deforestation in Asia is a major regional issue which, when coupled with seasonally variable river flows, has direct and profound impacts on floodplain residents. Given the extent of human misery caused by annual floods along major Asian rivers (most of which drain degraded catchments), the desire to limit peak flows by trapping floodwaters behind huge dams is understandable. In essence, greater frequency and intensity of flood flows are an inevitable result of deforestation. In turn, floods encourage the construction of protective dams that further alter the natural hydrological regime. The trend in Asia during recent years has been towards more and bigger dams, culminating in the world s largest dam, the Three Gorges Scheme on the Chang Jiang. Approximately 65% of the global total of large dams ($\geq$15 m tall) is situated in Asia; China has almost half of these, plus 10 major dams ($>$150 m tall). India (second in Asia and fifth in world ranking) has over 1100 large dams, and seven major dams. Dam building is not solely a response to floods. Other benefits include storage of irrigation water, and generation of hydroelectric power. The Mekong, for instance, has vast potential generating capacity. In 1994, the Mekong Commission (an autonomous coordinating committee set up by the riparian states) identified 12 sites for dams (most with planned outputs $>$10 000 MW) along the river mainstream in Laos, Thailand and Cambodia (Figure 1).

RIVER REGULATION AND DAMS

The planned construction of a dam array along the Mekong mainstream provides a good example of the potential effects of river regulation on fishes. Changed floodplain inundation patterns, combined with altered flow and temperature regimes, may suppress fish migration and breeding. Mainstream dams will obstruct the passage of long-distance whitefish migrants, including species (such as the pangasiid catfishes) that form the basis of Mekong wild-capture fisheries (for details, see Roberts, 1995). The greatest impacts of the dams will be felt by species confined to the Mekong. Among them are *Pangasius gigas* and *P. kremp* (Pangasiidae), the carps *Probarbus labeamajor* and *Aaptosyax grypus* (a 1.3 m long predator!), and the endangered freshwater herring *Tenualosa thibaudeaui*. They could be driven to extinction by a single mainstream dam. The life history of *Pangasius gigas* the giant 3 m Mekong catfish is obscure, but journeys upstream to Yunnan Province (China) have been mooted. This catfish was once the basis of an important fishery in Cambodia because oil could be extracted from its fatty flesh. Populations began to decline decades ago, and the fishery has collapsed in recent years.

One major dam proposed for the Mekong Basin would block the Tonlé Sap River, connecting Le Grand Lac to the Mekong (Figure 1). A dam on the Tonlé Sap River would impact fish production through changed floodplain inundation patterns, and exacerbate ongoing degradation and sedimentation in Le Grand Lac (see above). Elsewhere in the Mekong Basin, evidence of damage to fisheries is evident at the Pak Mun Dam, Thailand. Fish populations declined from 1991 (when dam construction began) until 1994 (when it was finished). Construction of Nam Theun Hinboun on the Theun River (a Mekong tributary in Laos) began in 1994, notwithstanding a prediction that the river below the dam would be reduced to a series of pools during the dry season with devastating consequences for many of the 140 fish species of the Theun Basin. Other impacts of dams result from the effects of thermal stratification, which occurs in impoundments behind large dams in tropical Asia. Water released from the hypolimnion is cool and oxygen-poor, or may be anoxic containing toxic hydrogen sulfide, with predictable consequences for the downstream biota.

The detrimental effects of dams on river fish are often ignored because of the view that impacts are more than compensated by fisheries in newly created impoundments. Such optimism is based upon a lack of understanding of fish ecology. Species adapted to the fluctuating discharge of a river will not thrive in a stagnant impoundment. Where high fisheries yields have been reported from Asian reservoirs, they depend on cage culture, stocking (usually of major carp), or introduction of exotic species. Such practices are invariably accompanied by a loss of native biodiversity.

Elsewhere in Asia, the conspicuous effects of mainstream dams on migratory river fishes are seen among the Acipenseriformes (sturgeons and paddlefish) of the Chang Jiang the largest river in Asia. Spawning migrations of the Chinese sturgeon (*Acipenser sinensis*) were blocked by the Gezhouba Dam (or Chang Jiang Low Dam) in 1981; fish passages were not provided. This species is anadromous, i.e., it spends part of its life in the sea but swims into rivers to breed. Flow alteration and changed sediment characteristics have reduced spawning success of Chinese sturgeons stranded below the dam. The Gezhouba Dam fragmented populations of the endemic Yangtze sturgeon (*Acipenser dabryanus*) also. It is now virtually extinct in downstream reaches, because it is a potamodromous species (i.e., it undertakes breeding migrations along but within the river) and populations below the dam are unable to complete their upstream breeding migration. Sedimentation has impacted stocks of remaining populations of the Yangtze sturgeon upstream of the dam. The anadromous Chinese paddlefish (*Psephurus gladius*: Polydontidae) has declined drastically in the Chang Jiang because the Gezhouba Dam prevents access to upstream spawning sites, and this species (one of two polydontids on the planet) is liable to become extinct. Furthermore, *Myxocyprinus asiaticus* the only catostomatid (sucker) species in the Old World became rare after completion of the Gezhouba Dam. The Three Gorges Dam may further jeopardize this, and other, potamodromous fish.

More than 3000 dams have been built along the Zhujiang (China s second largest river) during the last 40 years. They have obstructed migrations by *Clupanodon thrissa* (Clupeidae), and stocks of major carp (including *Cirrhinus molitorella*) have fallen to levels where they no longer sustain a viable fishery (Liao *et al.*, 1989). The abundance of the Chinese sturgeon has been greatly reduced, which has conservation implications as this fish is confined to the Zhujiang and Chang Jiang. In the Dongjiang, a major tributary of the Zhujiang, catches of the anadromous clupeid *Tenualosa reevesii* during the 1980s were only 20% of those 20 years earlier; it has been eliminated from parts of the river. Landings of the related *Tenualosa (= Hilsa) ilisha* dwindled to virtually nothing after completion of the Farakka Barrage on the Ganges in 1975. Similar consequences followed obstruction of migration routes by the Chenderoh Dam on Sungai Perak, Peninsular Malaysia. Between 1971 and 1980, catches diminished (Figure 2) and the availability of commercially important fishes fell from nine species to three. Among them, *Probarbus jullieni* (Cyprinidae) occurs in only one other river in Malaysia; it has also been eliminated from the Chao Phraya River (Thailand), and is threatened by dams along the Mekong. The impacts of river regulation involve not only barriers to longitudinal migration but also limitations on lateral movements. Fisheries in the Jamuna River (Bangladesh) have declined by more than 50% since 1983 because flood-control embankments reduce fish access to floodplains. Similarly, the major carp fishery of the Ganges practically disappeared after seasonal inundation of the floodplain was blocked. Along the Indus too, irrigation schemes have led to diminished fish stocks because of inadequate consideration for their need to pass dams, weirs and barrages.

Fish ladders which can mitigate the impact of dams on migrants are not widely used in Asia, and development of passage facilities has scarcely been addressed.

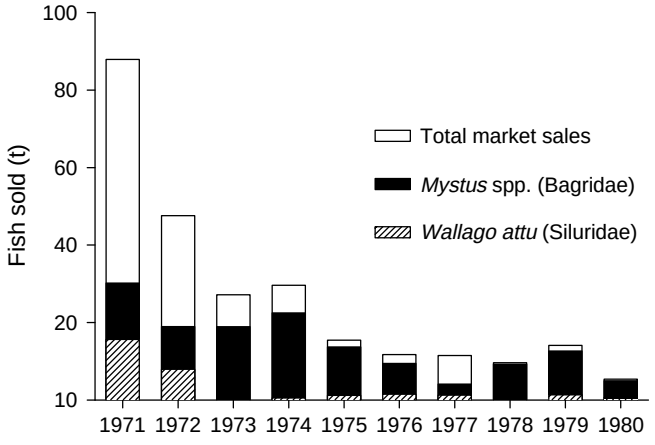

Figure 2 Market sales of river fishes in Perak State, Peninsular Malaysia, 1971–1980. (Data from Khoo *et al.*, 1987)

Fish ladders seem likely to have limited success because most Asian fishes do not jump. Moreover, ladders designed for species (such as north-temperate salmon), which swim upstream, do not allow for the fact that potamodromous Asian fish make downstream migrations as adults. Fishes on return migrations must pass through the dam turbines. Nevertheless, fish passes have been effective in facilitating migration past some dams on rivers in China (Jiangsu Province). Other conservation initiatives include opportunities arising from the Bangladesh National Flood Action Plan to manage capture fisheries through controlled flooding. Potential strategies include the design of flow regulators operated to give adults of major carp access to spawning grounds. Appropriate application of controlled flooding or drainage could permit the passage of water containing carp spawn and fry in a fish friendly manner.

POLLUTION

Water quality varies considerably throughout tropical Asia, but the region s major rivers are among the most degraded in the world. Anti-pollution legislation is in place in some countries, but is weak and/or poorly enforced (Dudgeon *et al.*, 2000). Pollution from agriculture and non-point sources is largely uncontrolled and, as cities and industries expand without adequate waste-treatment facilities, rivers receive increasing quantities of effluent. Many rivers are oxygen-poor for much of the year, but habitat deterioration is especially apparent during the dry season when water flows are insufficient to dilute pollutants. In some instances e.g., Peninsular Malaysia some rivers are so severely degraded that fisheries have collapsed. The situation is especially bad in China where, by 1995, some 80% of the 50 000 km of major rivers were too polluted to sustain fisheries (FAO, 1999). Fish kills (due to industrial wastewater, pesticides, etc.) occur frequently during the dry season, and fish have been entirely eliminated from more than 5% of total river length. Lesser tributaries tend to be more heavily polluted than the main channels (where dilution of contaminants is greater), but even in the mighty Chang Jiang (which once produced 70% of China s freshwater catch), landings fell by half (from 458 000 to 226 000 t) between 1954 and the late 1970s (before the Gezhouba Dam was completed) and have declined ever since. Things are no better in India. The Ganges ranks third in the region by flow volume, yet is probably the most polluted large Asian river. Population densities in the catchment are high, and 25% (600 km) of the river course is grossly polluted by human and animal wastes, as well as industrial effluent. Fish kills are common. Most industries discharging into the river lack waste treatment plants in working order, and some cities along the river (e.g., Varanasi) lack sewage treatment facilities entirely.

In short, most of the major rivers of Asia, as well as a host of minor streams, are grossly polluted. The impacts on the aquatic biota are manifest, and do not require emphasis here. Unfortunately, the political will to control pollution in Asia appears weak, and is likely to remain so as long as economic growth and the attitude of develop now, clean up later remain priorities for Asian governments.

OVERFISHING

Asia is responsible for around 64% of the global total of inland fisheries landings, although it only constitutes 20% of the world continental area (FAO, 1999). China, India, Bangladesh and Indonesia are the top four most important inland fishery countries, with Thailand ranking seventh. What does this indicate about the state or significance of river fisheries? Available figures do not separate yields of aquaculture-based fisheries and enhanced fisheries (where stock are added to water bodies) from natural capture fisheries, nor do they distinguish reservoir from river fisheries. Moreover, the dispersed and informal nature of many fisheries leads to under-reporting of landings. Subsistence fisheries are rarely included, and rivers may yield twice as many capture fishes as are actually reported. Nevertheless, one thing is clear. High catches in Asia reflect heavy exploitation of virtually all freshwaters, plus a substantial long-term increase in the contribution of aquaculture-based and enhanced fisheries to the total. This supplementation has permitted increased yields from certain Southeast Asian countries (Indonesia, Thailand, Laos: Figure 3), although this upward trend has not occurred everywhere (e.g., Vietnam, the Philippines).

There are many anecdotal accounts of declining stocks, but detailed fisheries statistics for Southeast Asian rivers are surprisingly scarce. Some monitoring of stocks would seem prudent. Laos, for example, is land-locked, and must depend entirely upon freshwater fisheries. Despite considerable inter-year variation, capture fisheries based on wild stocks appear to be at or exceeding the limits of sustainable yield. Declines in the average size of fish landed, attainment of maturity at a smaller body size, and reductions in catch per unit effort are among the signs that these fisheries are overexploited. Further consequences include altered community structure, diminished production, and damaged stocks.

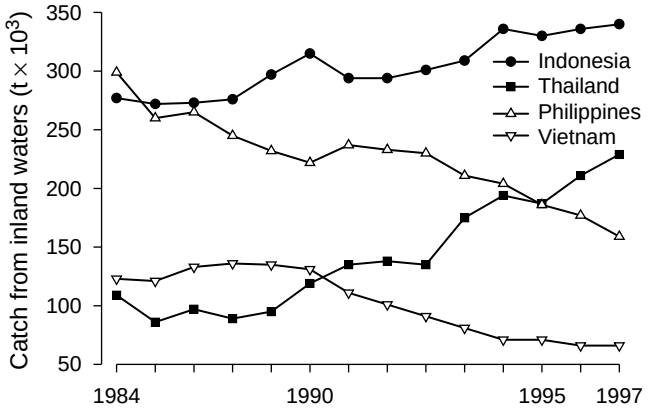

Figure 3 Annual inland fisheries landings, 1984–1997, in selected Asian countries, including yields from aquaculture/enhanced fisheries as well as natural capture fisheries. (Data from FAO, 1999)

The effects of overfishing first become manifest among large species. Populations of the 1 m long cyprinid, *Probarbus jullieni*, in Peninsular Malaysia were devastated by capture of egg-bearing individuals during upstream migrations (before passage was blocked by the Chenderoh Dam, see above). Reductions in *Probarbus jullieni*, *P. labeamajor* (which reaches 80 kg), *Catlocarpio siamensis* (120 kg, formerly the basis of an important fishery), and *Pangasius gigas* (300 kg), apparently due to overfishing, have occurred in Laos, Cambodia and Thailand. Similarly, overfishing in east Sumatran rivers threatens freshwater shark (*Wallago attu*: Siluridae) which has been exterminated over part of its range (see also Figure 2). Some of the reduction in Chinese paddlefish populations in the Chang Jiang (see above) is attributable to overfishing also.

Dramatic declines in capture fisheries such as a 40% reduction in landings by Laotian artisanal fishers between 1984 and 1992 may reflect the use of explosives. Increased availability and use of synthetic chemicals, rather than natural poisons (such as rotenone which must be extracted from plants), may be a contributing factor. Motorboats and refrigeration technology also allow the exploitation and marketing of previously inaccessible stocks. Significant declines in the major carp recruitment in the Zhujiang reflects the use of ever-finer meshed nets and overfishing of spawning grounds, combined with the application of poisons, explosives and electric shocking. Overfishing cannot, however, be separated from the damaging effects of dams and pollution in the Zhujiang, where toxins cause periodic fish kills. Similar caveats apply to rivers such as the Chang Jiang (see above).

CLIMATE CHANGE

The effects of global climate change on flow regimes in rivers is of considerable significance because the influence of water quantity on the life history of tropical fishes seems to parallel the importance of temperature to fishes in temperate latitudes (Meisner and Shuter, 1992). Climate change scenarios derived from general circulation models (GCMs) of the atmosphere suggest that increased carbon dioxide concentrations (and aerosols) would alter rainfall across the tropics. Different GCMs predict different directions and magnitudes of change. Wet seasons may get wetter

or drier; likewise, dry seasons may get wetter or drier. One recent study projects changes in wet-season rainfall over tropical Asia in the range of −5% to +18% (McLean *et al.*, 1998); anticipated dry-season changes are smaller and less consistent. A greater frequency of heavy rainfall or extreme precipitation events can be expected also (e.g., Bhaskaran *et al.*, 1995; Bhaskaran and Mitchell, 1998). Specific predictions for the Mekong include greater seasonal differences in flows and delays in the flood peak (Riebsame *et al.*, 1995); a later onset of the monsoon is seen in a GCM developed for India also (Bhaskaran *et al.*, 1995). Higher temperatures will increase evapotranspiration and may reduce dry-season flows; the magnitude of these projected changes in discharge vary linearly with rising temperatures. Note that the magnitude of annual river discharge may not change under some GCM scenarios because wet-season increases could offset lower flows during the dry season. Nevertheless, because extreme flow events will become more frequent, climate change may stimulate additional dam construction for flood control and irrigation. Substantial uncertainties are added to predictions of climate change and altered river discharge derived from GCMs because of likely interactions with the effects of widespread deforestation in Asia (Fu *et al.*, 1998; Vorosmarty *et al.*, 1998). If wet-season runoff increases (as predicted by most GCMs), sediment loads in rivers will rise, and deforestation will exaggerate this effect.

Regardless of the details of GCM projections, changes in discharge magnitude and seasonality of tropical Asian rivers will alter the extent of floodplain inundation and degrade the quality of fish habitat during non-flood periods. The implications for biodiversity are significant because fish catches (and hence secondary production) from tropical rivers are positively correlated with the extent of inundated floodplain, and fluctuations over time occur in response to inter-annual variations in flood peaks (Welcomme, 1979). The projected increase in frequency of extreme flow events will therefore tend to increase the variability of fisheries yields from rivers. If additional dams and flood-control projects are built in response to climate change, their impacts on fishes (and fisheries) will be detrimental. However, the magnitude of that effect is hard to estimate because, in most instances, the influence of existing structures has not been assessed in detail. Dams appear to have had deleterious effects on ecosystems, so we can assume that further discharge alterations caused by climate change, or the construction of additional dams, will reduce biodiversity further.

CONCLUDING REMARKS

Threats to fishes, generated by a combination of anthropogenic factors, have important implications for riverine biodiversity throughout tropical Asia. The limited data on fisheries landings indicate declines in natural capture fisheries. While figures collected from markets underestimate total yields, long-term population trends are unlikely to be affected by this bias. Data on fisheries in individual rivers or drainage basins, reported at the level of species or species groups, are needed for ecological interpretation of ongoing environmental change. Their lack limits our ability to take remedial action or mitigate anthropogenic impacts. Overfishing is clearly a contributory factor in reduced yields and is, in theory, amenable to regulation or control. However, environmental degradation and loss of fish habitats is a critical problem throughout much of Asia, and is the overriding threat to riverine biota. Reversal of prevailing trends is a major, urgent challenge for the 21st century, if we want to ensure a future for Asian river fishes.

Food Consumption Patterns and their Influence on Greenhouse Gas Emissions

Annika Carlsson-Kanyama

Environmental Strategies Research Group, Stockholm, Sweden

Emissions of greenhouse gases and energy use related to food consumption and production are explored and related to food products, consumption patterns and food trends. The relative emission contributions over the life cycle of food products vary greatly depending on the food product. For some products, processing dominates while for others, farming is the main contributor. Total emission levels over the life cycle vary greatly between food products with similar nutritional qualities. Substitutions leading to lower emission levels include more vegetables grown in the open and less in greenhouses, less meat and more legumes and more fresh and less tinned food. Trends in food consumption patterns, on the other hand, include more meat consumption, more fast and frozen foods, i.e., food almost ready for nal consumption, and more fresh food. In northern Europe, possibilities for production of fresh vegetables may increase as a result of climate change. In other parts of the world, the consequences of this change for food production and consumption may be far less bene cial.

HOW FOOD CONSUMPTION PATTERNS INFLUENCE CLIMATE CHANGE

Emissions of the major greenhouse gases carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O) and hydrofluorcarbons (HCFCs) are closely associated to food production and consumption. During the life cycle of food, which includes crop cultivation, animal husbandry, processing, transportation, storage, preparation and waste disposal, numerous human-induced activities cause emissions of these gases.

It is possible to calculate the greenhouse gas emissions from various foods over their life cycle so that emissions levels for various diets or food products can be compared. Such information can, and is, being used in discussions about how changing food patterns may, or may not, result in decreasing emission levels (Brower and Leon, 1999; VROM, 1999; Dahlin and Lindeskog, 1999).

When such estimates are being made, the following emissions are commonly considered:

- CO_2 fuel cycle emissions from fuels necessary to run the lorries, planes, ships, and tractors that are necessary for producing and transporting food. CO_2 fuel cycle emissions from food processing plants and fodder factories and from the fuels used for generating the necessary electricity for storage, heating, stables and electrical irrigation pumps are included as well. Net emissions of CO_2 that result from clearing forests for the purpose of cultivating food and emissions of CO_2 when organic soils are used for food production should also be considered.
- Emissions of refrigerants (including production emissions of refrigerants) from leaking transport refrigeration equipment in lorries, planes and ships and from refrigeration equipment in stationary storage facilities kept in warehouses, at the retailers and in people s homes.
- CH_4 emissions from hydropower dams used for producing the electricity needed for food production. CH_4 released from domestic livestock enteric fermentation, manure management and flooded rice fields are also part of the analysis.
- Process emissions of N_2O during the manufacturing of nitrogen (N)-fertilizers and N_2O-N yields from farmland as a result of application of nitrogen-fertilizers. N_2O emissions during storage of manure are considered as well.

Thus, food consumption directly and indirectly causes emissions of both energy-related greenhouse gases and greenhouse gas emissions from other sources during all steps in its life cycle. Some estimates of greenhouse gas emissions from various foods and diets have been made with the conclusions that i) relative emissions and energy

use during the life cycle vary depending on product, ii) different properties of foods result in large differences in greenhouse gases during their life cycles. Therefore diet is important for the total emissions from consumption patterns.

Relative Emissions and Energy Use During the Life Cycle of Products

Greenhouse gas emissions over the life cycle of foods can be distributed in very different ways depending on the choices of technologies for farming, transportation, storage etc., and because of the degree of packaging, processing and storage. This is illustrated in Figure 1 where the relative energy inputs over the life cycle of hamburger, bread, onions, pickled cucumber and lettuce are compared. (Energy use is often a good indicator of CO_2 emissions, the major greenhouse gas.) The result is that primary production, including crop farming and animal husbandry, dominates for hamburger, lettuce and cheese. This is because of the high use of fossil energy for heating greenhouses where the lettuce is produced and because of the high-energy use associated with feed production for cattle. For freeze-dried onions, bread and pickled cucumbers, the most energy-demanding stage in the life cycle is processing. This is because the relatively high energy consumption associated with baking, freeze-drying and pickling. These processes are applied to products with low energy demand during primary production and storage.

Mattson (1999) showed that the life cycle greenhouse gas emission profile of carrot purée was dominated by the processing stage due to the high-energy requirements for fabricating the purée from raw carrots. In another study of a cereal-based baby food product, the same author showed that the processing stage dominated the life cycle greenhouse gas emission profile together with the agricultural phase. The agricultural phase included dairy farming for obtaining the milk powder necessary for producing the baby food (Mattson and Stadig, 1999). Dairy cows emit CH_4 and Kramer (1999) suggested an emission factor of 27 grams of CH_4 kg^{-1} raw milk. Andersson (1998) analysed ketchup during its life cycle and showed that food processing and packaging made large contributions to global warming because of their high consumption of fossil fuel. The tomatoes were grown in the open in her study.

Emission Levels and Energy Use During the Life Cycle of Various Foods

There are some fundamental differences between the magnitude of greenhouse gases that can be emitted during the life cycles of foods. Foods that have similar nutritional contents can show very different life cycle emission profiles and this means that there are considerable opportunities for lowering greenhouse gas emissions related to food consumption by changing diet. This has been shown in a few studies that are discussed below.

Using vegetables grown in the open instead of vegetables grown in greenhouses would lower life cycle

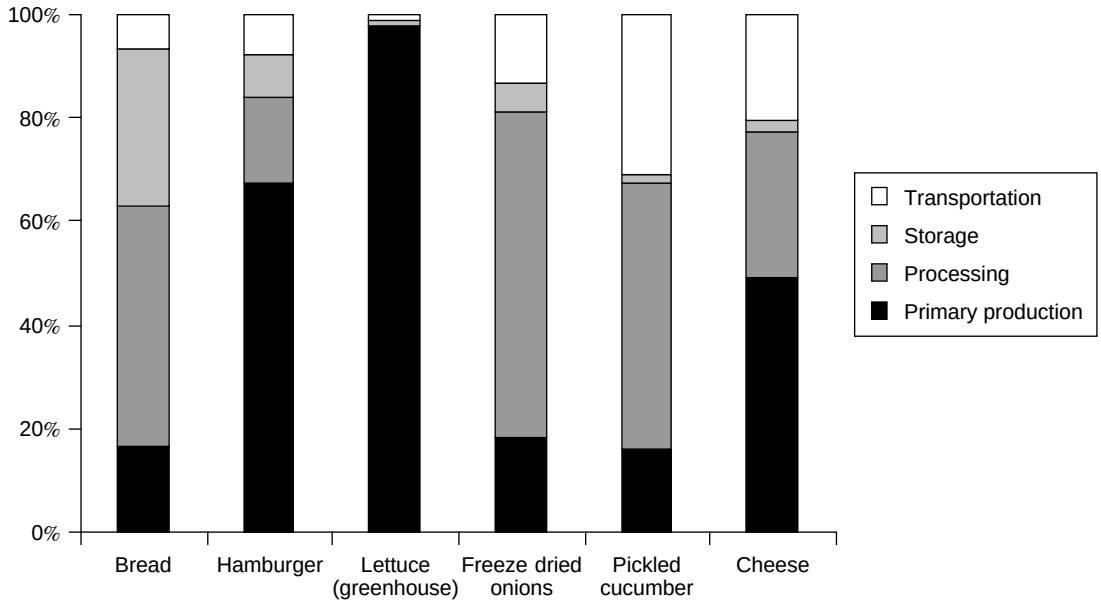

Figure 1 Distribution of energy use during the life cycle of hamburger bread, hamburger, lettuce grown in greenhouse, freeze dried onions, pickled cucumber and cheese (calculated from Carlsson-Kanyama and Faist, 2000)

emissions of greenhouse gases considerably (Carlsson-Kanyama, 1997). When compared by unit weight, open-grown carrots emit only 10% of the greenhouse gases emitted by tomatoes grown in greenhouses (*see* Greenhouse Food Production (Agriculture Intensive), Volume 3).

Coley *et al.* (1998) analysed the life cycle energy used for supplying the UK population with food. They calculated the energy used in the agricultural, transportation and retail sectors for various foods and coupled that information with food consumption data from over 3000 individuals. Coley called energy used in agricultural, transportation and retail sectors for the *embodied* energy of food. The large range in the embodied energy for diets was surprising, according to the authors. Some individuals consumed food with five times more embodied energy than other people did. The authors concluded that there were potentials for significant reductions in fossil fuel related greenhouse gas emissions by simple changes in diets but did not explore these possibilities.

Carlsson-Kanyama (1998) analysed the life cycle greenhouse gas emissions from four different meals consumed in Sweden that had the same nutritional content although they were composed of six different ingredients, carrots, pork, rice, dry peas, tomatoes and potatoes. Table 1 shows the total greenhouse gas emissions for these foods. Both life cycle emissions of greenhouse gases and life cycle energy use were lowest for the vegetable products: carrots, potatoes and dry peas. These foods were grown in open fields and mainly in Sweden. Life cycle emissions of greenhouse gases were highest for rice, pork and tomatoes. Most tomatoes were assumed to have been grown in greenhouses in Sweden or nearby countries, while rice was produced in countries distant from Sweden on irrigated fields. Figure 2 shows the emissions of greenhouse gases in grams of CO_2 equivalents for each of the different meals in Carlsson-Kanyama s study. The meals a d in Figure 2 can be characterised in the following manner. Meal a is purely vegetarian with ingredients mainly from the domestically produced foods carrots, potatoes and dry peas. Meal b is also vegetarian, but with the exotic ingredients rice and tomatoes in addition to dry peas. Tomatoes are considered exotic because either they have to be imported from southern Europe or else grown in greenhouses. Meal c is solely based on animal and exotic foods: rice, tomatoes and pork while meal d contains only domestically produced

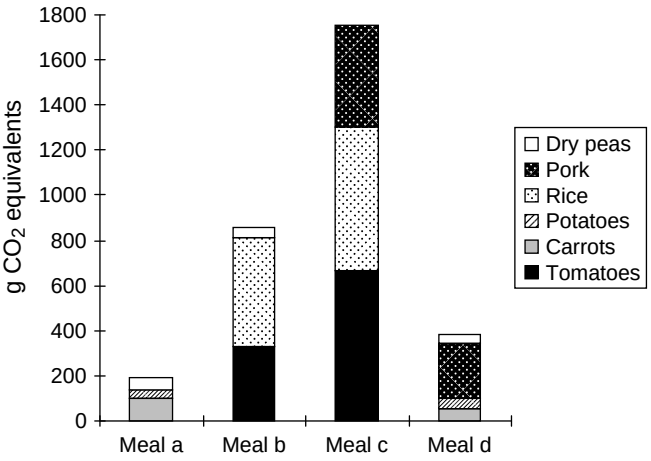

Figure 2 Life cycle emissions of greenhouse gases in CO_2 equivalents from four different meals with the same energy and protein contents (Carlsson-Kanyama, 1998)

food of both animal and vegetable origin. Figure 2 shows that emissions of greenhouse gases during the life cycle of the four meals differ substantially. The animal exotic meal (meal c) emits 1800 g of CO_2 equivalents while the vegetarian domestic meal (meal a) only emit 190 g of CO_2 equivalents. This makes the animal exotic meal nine times more polluting than the vegetarian domestic meal.

Kramer *et al.* (1999) calculated the life cycle emissions of greenhouse gases related to Dutch household food consumption and found that food products from cattle farming determine the CH_4 emissions, while food products from agriculture determine the N_2O emissions. They showed that differences in greenhouse gas intensities within food product categories and between food product categories are significant and that these differences offer possibilities for reduction options. For example, the CO_2 intensity, measured as kg Dfl^{-1}, was 0.59 for minced meat but only 0.17 for carrots and tubers. Examples of reduction options given by the authors are shifting from glasshouse vegetables to vegetables grown on the open ground, substituting meat for eggs, pulses and nuts and substituting tinned, bottled, or frozen vegetables for fresh vegetables. The authors also showed that for food products from cattle farming determines the total life cycle emissions of CH_4 resulting from food consumption patterns while products from agriculture determine the life cycle emissions of N_2O.

Table 1 Life cycle emissions of greenhouse gases in CO_2 equivalents for carrots, tomatoes, potatoes, pork, rice and dry peas consumed in Sweden (Carlsson-Kanyama, 1998)

	Carrots	Tomatoes	Potatoes	Pork	Rice	Dry peas
g CO_2 equivalents kg^{-1}	500	3300	170	6100	6400	680

TRENDS IN FOOD PATTERNS AND HOW THEY CAN INFLUENCE OR BE INFLUENCED BY CLIMATE CHANGE

Historically patterns of food consumption have changed from a diet based mainly on locally produced foods to a diet where exotic fruits, vegetables, spices, meat and processed food are becoming more commonplace (Figure 3).

The global change impacts resulting from the increased meat consumption have been much discussed (e.g., Wirzenius, 2000; Goodland, 1997). They include increased emissions of methane from the digestive tracts of animals, clearing of virgin forests for obtaining grazing land and cultivation of lands not suitable for crop farming with resulting losses of topsoil. Wirzenuis (2000) estimated that animal food systems accounted for roughly two-thirds of the total appropriation of global biomass while their contribution to human diet was merely one-tenth of the total. Such results fuel discussions about possibilities for shifting diets in order to safeguard both the environment and mankind. However, there are other food consumption trends in developed countries that have the potential for changing the amount of greenhouse gases currently released during the life cycle of diets. Those who can afford it in the developing world often emulate consumer culture in the developed countries (Gallagher, 1997), so trends in developed countries are of utmost importance for the whole of the global community. The ongoing nutrition transition among urban populations in the third world includes, among other changes, an increased consumption of meat (Popkin, 1999).

Food patterns depend on a number of factors. The state of the ecosystems is certainly very important for the food supply but wealthy urban populations, a category to which most people in the developed world belong, are not the first to see their food supply affected by environmental change. In the short run, other factors have a far greater effect on their food patterns and that includes

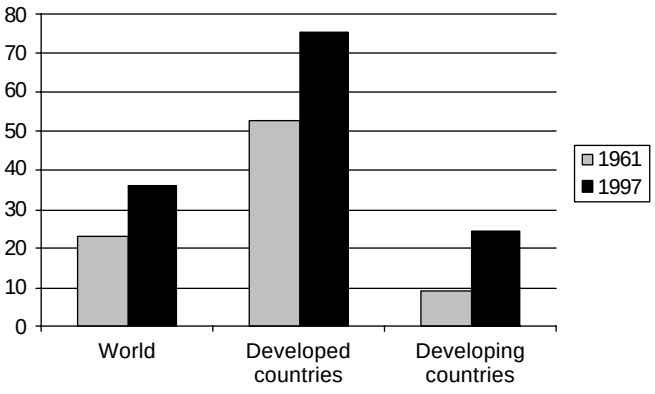

Figure 3 Meat supply in 1961 and 1997 in kg meat person^{-1} year^{-1}. For the whole world and for developing and developed countries (FAO, 2000)

the available food technology, expectations from food suppliers expressed through advertising and marketing and the time and knowledge people have of food preparation. A consistent trend in many developed countries is that knowledge about food preparation and food handling is on the decline, resulting in more cases of food poisoning (Carlsson-Kanyama, 1999).

Food suppliers in Sweden are strongly influenced by trends in the rest of Western Europe and the US (Carlsson-Kanyama, 1999). They believe in some major developments that could impact levels of greenhouse gases emitted during the life cycle of diets in the future.

The major trend is that the supply of fast foods is going to increase in the future food market. Increasingly hurried lifestyles of consumers is considered to be an important factor in this trend, resulting in an increased supply of food that is quick and easy to prepare. Along with an increased supply of more uncomplicated foods, there will be more foods perceived as healthy, according to the same food suppliers. This means more chilled but fewer canned and frozen products. The food suppliers, who do not expect time-starved future consumers to wait for frozen food to thaw, regard the fact that chilled products take less time to prepare as an additional advantage. Partly as a result of the trend towards healthier food, many interviewees also believed in an increased and diversified supply of fruit and vegetables, while many expected meat consumption to decline (Carlsson-Kanyama, 1999).

There are many examples of substitutes for food that require skill and time to prepare, and that emit more fossil fuel related CO_2 during their life cycle than their precursors. Examples are rice versus potatoes or tomatoes versus carrots (Table 1). Rice requires less skill to prepare than potatoes because cooking time can be predicted with higher accuracy and tomatoes require less skill than carrots because carrots have to be ground or boiled. But food is sometimes prepared with equal or less fossil fuel inputs in industries than in homes. A study of energy use during the life cycle of pea soup showed that whether the soup was cooked at home or industrially was insignificant. What really mattered was how much meat the pea soup contained, how the soup or ingredients had been transported to the consumer s home and how much was discarded in the household. A growing numbers of unskilled consumers could also make inefficient use of food resources leading to more organic waste. Food preparation by industry could then be an advantage provided that waste was re-used or re-cycled efficiently. But to what extent will food that is faster and easier to prepare entail longer transportation distances, more elaborate processing and longer storage times? The impact of such activities may be significant in evaluating the impacts of products during their life cycle. There are many

ways of imagining a future supply of faster, easier food: from the local food industry using organically produced food to large-scale industries using food of global origin. Surely, the environmental consequences of these alternatives will differ, as will the consequences for consumer protection.

Ecosystem alteration caused by climate change will, in the long run, significantly alter regional possibilities for food production. For example, crop zones in Western and Northern Europe will expand enabling, for example, successful production of wheat in the northern coastal zone of Sweden where such production is today severely constrained due to the cold climate and short cropping season (Raisanen *et al*., 2000). The possibility of expanding the production of more exotic crops in Northern Europe also seems likely. Examples are maize and grapes, while other examples may be a northern extension of vegetables and fruits cultivation, such as cucumbers, cauliflower and cherries.

These new possibilities certainly seem to fit well with anticipation for an increased consumer demand for fresh and healthy food. In this scenario, local production of fruits and vegetables in Western Europe could increase with beneficial consequences for fossil fuel related emissions from vehicles. Unfortunately, climate change is predicted to have far more serious consequences in parts of the world where many consumers do not have the purchasing power to demand other than locally produced food. With a collapse of local fisheries depending on coral reefs (World Resources Institute, 2000), for example, food patterns common among coastal communities in developing countries could change to diets with less high quality protein. Whether or not this will be of concern for affluent people in Western Europe, who could benefit from the anticipated changes, is an open question. Food patterns now and in the future can both influence and be influenced by climate change. For some people, climate change will offer new possibilities for obtaining a diversified supply of locally produced foods. For others, consequences of this change can threaten their very existence by changing food patterns to less nutritious ones.

Forest Logging Systems in Tropical Countries: Differential Impacts

Abdul Rahim Nik
Forest Research Institute Malaysia, Kuala Lumpur, Malaysia

Sustainable production of tropical forests has attracted much debate and become an international issue. This is because tropical rain forests are not only unique in many respects, but also the demands placed on them are intense and increasing in complexity. The growing population in many countries of the humid tropics continues to exert tremendous pressure on the forests for various uses, increasing fuel-wood requirements, expansion of agricultural land, clearing for settlement and commercial logging. By the same token, forests are also susceptible to natural disturbances such as res, landslides, insect attacks and diseases. In addition to tangible bene ts, forests of various types provide other environmental services such as watershed protection, soil conservation, a supply of fresh water and carbon sequestration.

While forest cover in many developing countries has been steadily decreasing, there has been a continued increase in demand for wood products. The global consumption of wood increased by 36% between 1970 and 1994 (FAO, 1997). Similarly, demand for fuelwood, which is the main source of energy for two- fths of the world's population, continues to grow by 1.2% per year.

Realizing the important role of tropical forest, heightened environmental awareness and public pressure have continued to exert in uences upon all aspects of the forestry sector: forest management, harvesting and post-felling operation and including trade. Recognizing that forests should be managed not only to ensure their productive functions, but also environmental services and social bene ts are sustained, has led to efforts to develop criteria and indicators for sustainable management (FAO, 1997). There is a concerted trend towards managing forests as ecological systems with multiple economic bene ts and environmental values.

SELECTIVE LOGGING SYSTEM

Currently, selective logging is practiced for the extraction of valuable timbers from tropical forests. This is so because of the high species diversity of tropical forests; only a small proportion of the trees are suitable for extraction during each logging phase, or rotation. Further, this system has the flexibility to manage highly variable forest conditions and changes in the socio-economic environment (Thang, 1997). While its implementation may vary from country to country, this system entails selection of felling regimes based on inventory data. Depending on the intensity of logging and the rotation time between logging operations, two selective logging systems essentially governed by the silvicultural systems, called the *monocyclic* and *polycyclic* systems, are commonly used. The former involves removal of up to 100% of commercial trees from the forest. The time between successive logging phases or logging cycles depends on the maturity of the main species felled. As the volume of timber removed can be as high as $120\,m^3\,ha^{-1}$, the potential damage to soil and residual trees is also substantial (Bruijnzeel and Critchley, 1994; Bruenig, 1996). Under the polycyclic system, highly selective removal of large trees of desired species is prescribed. Thus, fewer trees and a lower volume of timber are removed, which amounts on average to 8 10 trees ha^{-1} or 20 $30\,m^3\,ha^{-1}$, respectively. Examples of such systems are the Selective Management System in Malaysia, Tebang Pilih Tanam Indonesia in Indonesia and CELOS in Surinam.

LEVEL OF FOREST DISTURBANCE

Since forest logging takes place in several forms and to ease the assessment process, Bruijnzeel (1990, 1992) classified impacts on forests into three levels of disturbance, namely low, intermediate and high. Low intensity disturbance is usually associated with a natural cause such as mortality or tree fall. The other levels of disturbances are associated with human-induced activities: selective logging shifting cultivation, forest plantation and permanent agricultural crops. Forestry activities should be described precisely before evaluating the environmental impacts of each activity. In general, forest logging may cause detectable changes in the environmental variables, depending on the intensity of disturbances and the extent of cover removed. By the same token, forest clearance and forest conversion to other land uses are expected to cause greater impacts on hydrology and soil erosion processes. With increasing emphasis on sustainable forest management, an improved harvesting technique known as *reduced impact logging* (RIL) is being implemented and promoted in various regions. The aim of this technique is to reduce damage on residual trees, soil disturbance, and impacts on wildlife (Sist *et al.*, 1998).

DAMAGE TO RESIDUAL TREES

The extent of damage to residual trees following forest logging or harvesting is critical, for it will determine the time of the next logging cycle. Previous studies showed that damage in conventional forest logging operations has been quite excessive, especially in areas with high logging intensity in which the percentage of damage may reach 30 70% (Nicholson, 1958; Fox, 1968; Dykstra and Heinrich, 1996;

Canonizado, 1978). In areas with lower logging intensity, damage to residual trees has ranged from 10 20%. Logging damage could be reduced by instituting pre-felling of climber cutting. However, with the adoption of RIL techniques, a remarkable reduction in residual tree damage can be attained from 50 200% (Johns *et al.*, 1996; Moura-Costa, 1997). In this instance, achieving a threshold of logging intensity should be promoted as suggested by Watanabe (1992), viz, stands at 30% of stand basal area.

EFFECTS OF FOREST CONVERSION AND FOREST LOGGING ON WATER YIELD

Most of the quantitative information regarding hydrological changes resulting from forest logging or forest conversion is based on catchment experiments usually conducted on relatively small watersheds of less than 250 ha in size (Hewlett, 1982). While there are many variations to conducting experimental catchment studies, a paired-catchment method is most commonly adopted. Nevertheless, one of the problems associated with catchment studies is a leakage problem especially in the case of small headwater catchments (Bruijnzeel, 1990).

The question of water changes after forest removal or land use change has been extensively assessed and reviewed in many parts of the world, including tropical countries (Bosch and Hewlett, 1982; Oyebande, 1988; Bruijnzeel, 1990, 1992, 1997; Bonell and Balek, 1993). The main objective of those investigations was to determine the effects of vegetation and natural plant cover removal, or modification on hydrological variables including water yields and flow regime. This issue has assumed greater importance as forestry and land use changes take place in upstream catchments that served as an important source of water supply for downstream users.

Results obtained from studies in temperate zones as well as in the tropics indicate that almost every well-designed experiment has shown increases in water yield as a response to forest cutting and, in general, the increase is proportional to the amount of canopy removed (Bruijnzeel, 1990; Oyebande, 1988, Table 1). Removing up to 40% of the standing trees causes increases in water yield ranging from 113 188 mm $year^{-1}$ or 59 85% $year^{-1}$ (Abdul Rahim and Harding, 1992). In other words, removal of forest cover generally leads to increased streamflow, while afforestation or reforestation with fast growing species on cleared lands leads to a decline in water yield (Oyebande, 1988). This increase may be permanent when converting tall forest to grassland or shallow rooted agricultural crops, or may be temporary in the case of conversion to tree plantations. With much effort given to reforestation programs in many developing countries in view of diminishing forest areas, more attention should be focused on this issue.

However, the above responses are generally applicable to forests at elevations lower than 1000 m above sea level which, in the humid tropics of southeast Asia comprise lowland and hill dipterocarp forests. Floristically, beyond that altitude, different forest types can be found, namely upper dipterocarp, oak laurel and montane ericaceous forests (Burgess, 1969), which are also known as tropical montane cloud forest (Studtmuller, 1987).

During the regeneration, or the recovery period, the time taken to recover to the pre-logging condition depends on the level of disturbance and the year-to-year variability of rainfall. Nevertheless, detailed information on this process is still limited and sometimes contradictory. The Berembun catchment study in Malaysia, showed that the water yield increment began to decline seven years after selective forest harvesting had extracted about 40% of the commercial stock (Abdul Rahim and Zulkifli, 1994). Similarly, Malmer (1993) found no trend in annual evapotranspiration for five years immediately after forest clearing in Sabah, Malaysia. On the other hand, Kuraji and Paul (1994) claimed that 3 5 years after logging activities in Sabah, the pre-logging water yield was attained. Under temperate conditions, it may take much longer to return to the pre-clearing level of streamflow.

EFFECTS OF FOREST LOGGING ON FLOW REGIMES AND FLOODING

In many places, dry-season flow is an important issue for water supply managers, particularly when the demands are high due to a protracted period without rain. During this period, baseflow and reservoir storage become the only sources of water to meet consumptive requirements of irrigation, domestic use and industry. In addition, a low-flow period is also critical from the water quality point of view, as pollutant concentrations generally become higher. Hence, the impact of forest activity on dry-flow conditions becomes a major concern, not only to forest managers, but more so to water supply engineers.

Evidence with respect to the effects of forest clearing on dry season flow in the tropics seems, at first, contradictory and ambiguous. On the one hand, there are reports of greatly diminished flows whilst on the other hand, significant increases have been observed. This is so because forest conversion has two opposite effects on water. First, it tends to increase runoff and decrease infiltration of water into the ground, mainly due to ground compaction and disturbance, which would lower the water table (Bruijnzeel, 1990). On the other hand, replacement of forest with shallow rooting vegetation with a lower transpiration rate tends to reduce groundwater loss and hence raise the water table. Nonetheless, in interpreting the above contrasting results, one has to take into account the prevailing climatic, pedological and hydrological setting of the area as well as

Table 1 Changes in water yield and stormflow response following logging (adapted from Bruijnzeel, 1990, 1992)

the way in which conversion and subsequent land use were carried out (Bruijnzeel, 1989).

Hydrological studies on selective logging in Peninsular Malaysia have clearly shown that increases in water yield following forest removal are largely associated with baseflow augmentation. This is so mainly because of the minimal disturbance to the ground and stream channels, except along forest roads and skid tracks. This, in turn, leaves surface infiltration relatively unaffected. Eventually, a greater recharge to groundwater may occur, resulting from reduced evapotranspiration and, ultimately, a larger baseflow.

There has been a protracted debate and popular belief regarding the role of forests, as to whether or not forest cover upstream areas at catchments will prevent floods downstream. Quite often, forest logging has been blamed for disastrous flooding downstream. For instance, monsoonal floods of the Ganges and Indus have been attributed to uplands tree cutting (World Water, 1981). Controversies arise mainly due to a misunderstanding on the biophysical relationships involved. Among pertinent questions are, for example, whether the perceived increase in flooding that follows forest clearing is due to the removal of tree cover itself or is due to abusive land use. Further, are both the upstream and downstream areas affected?

Scientific evidence supports a link between deforestation and flooding at the local level within a drainage basin of less than 50 000 ha (Bruijnzeel and Bremmel, 1989). In small watersheds, increases in water yield resulting from forest conversion translate directly into increases in stormflow. Individual sub-watersheds will tend to flood in sequence, as storms pass segmentally rather than simultaneously. It has been shown that after forest clearance, peak discharge and stormflow volume significantly increase due to the effect of an increase in soil wetness. However, in the case of selective logging, the effects on peak discharges related to soil moisture would be less significant.

EFFECTS OF FOREST LOGGING ON SOIL EROSION AND SEDIMENTATION

In discussing the impacts on soil erosion and sedimentation, it is instructive to make a distinction between on-site erosion and off-site or downstream effects. The former involves a smaller spatial scale such as a field or hillslope, which produces a much faster runoff while the latter affects a larger area farther downstream. This downstream effect may take a long time to be reflected in a large watershed (Pearce, 1986). The eventual effect, when eroded soil particles are washed downstream, is to reduce the life of reservoir and irrigation systems, diminishing their efficiency, and thus increasing the costs of maintenance.

Interesting results have been synthesized by Wiersum (1984) on surface erosion under various tropical forests and tree crops. Ground cover, rather than canopy extent, is the main cause of surface erosion. Removal of understory vegetation may lead to slightly greater erosion rates, but soil erosion increases markedly upon removal or destruction of the forest litter layer. When trees are harvested, their removal requires trails, skid tracks, and roads, which if not planned and constructed properly, will cause serious erosion and sedimentation. In many instances, the major cause of soil erosion is usually associated with road construction rather than the land use change itself. In Malaysia, the amounts of soil erosion arising from forest roads and skid tracks in the first year after logging are 13 tons ha^{-1} and 10 tons ha^{-1}, respectively. However, the rate of erosion is drastically reduced to 3 and 2 tons ha^{-1} $year^{-1}$ in the second year (Baharuddin, 1995), mainly due to the rapid recovery of undergrowth.

Selective forest logging in the Berembun catchments, Malaysia, led to minimal increases in sediment yield concentrations, and thus sediment yield under both the usual commercial and the supervised commercial types of logging (Baharuddin, 1988). This was because of the low logging intensity as prescribed in the selective logging system coupled with the institution of conservation measures. On the other hand, forest logging in Ulu Segama, Sabah and Hulu Langat, Selangor produced much higher sediment yields (Douglas *et al.*, 1993 and Lai, 1993, Table 2).

To fully assess the impact of land use change from forest to other types, it is necessary to evaluate the link between induced erosion and sedimentation. This depends on two factors the *sediment delivery ratio* and the background level of sedimentation (Chomitz and Kumari, 1996). Essentially, only some of the eroded soil ends up in stream channels and rivers; the reminder is trapped or redeposited farther downslope. Sediment delivery ratio varies inversely with the catchment size and a ratio 0.3 is assumed for basins on the scale of hundreds of square kilometers. Background sedimentation varies remarkably, depending on local geology and the state of on-site land use. Factors to be considered include land management practices, human settlement, extent of road area and topographical features.

EFFECTS ON WATER QUALITY AND THE NUTRIENT BUDGETS

Water Quality

Forest logging affects stream water quality through physical, geochemical and biological processes. Removal of forest cover, especially the undergrowth and litter layer, will not only induce erosion but also enhance leaching of chemical elements. Additional sources of organic matter in the form of logging debris, coupled with greater exposure to sunlight, will enhance microbiological activity, leading to higher rates of decomposition, mineralization and nitrification.

Table 2 Impacts of forest conversion and forest logging activities on sediment yield[a]

	Location	Type of land use change	Area (ha)	Annual rainfall (mm)	Sediment yield (mt ha^{-1} $year^{-1}$) (before)	Sediment yield (mt ha^{-1} $year^{-1}$) (after)
1	Sungai Tekam, Pahang					
	Catchment A	Secondary Forest to cocoa	47	1916	0.17	0.50–1.05
	Catchment B	Secondary Forest to oil palm	96		0.42	1.05–4.14

[a] *Sources:* DID (1989); Baharuddin (1988); Douglas *et al.*, (1993); Lai (1993) and Malmer (1993).

The impact of selective forest logging, which removed about 40% of the standing trees in the Berembun, Malaysia, resulted in increases of pH, electrical conductivity (EC) and water hardness (Zulkifli *et al.*, 1993). The largest increases were observed for suspended solids and turbidity by 12- and 9-fold, respectively, in the first year after logging. Similar increases in chemical concentrations were also observed particularly for alkalinity, silicate, iron (Fe), potassium (K) and sodium (Na). However, recovery to pre-logging conditions was attained in between three and five years but increases Fe and K tended to be more prolonged. The impacts were most pronounced during and immediately after storms.

Converting about 60% of a logged-over forest in the Tekam catchment in Pahang, Malaysia resulted in two-fold increases of EC, which was sustained for three years (DID, 1989). The higher EC reflects an overall increase in ionic concentrations. The other noticeable increases were for Fe and K during the land preparation and planting stages. Bare ground resulting from road construction was the major source of Fe. On the other hand, K might be released from soil minerals and decomposing biomass. Following establishment of a forest plantation at Mendolong, Sabah, Malaysia, considerable increases in EC and K were also observed (Malmer, 1993).

Although water quality degradation due to forest operations is inevitable, it is possible to reduce the impact to a manageable level under well-planned logging and by strict adherence to conservation measures. Proper road alignment and buffer strips are the main considerations for reducing logging impacts. In the case of forest conversion/clear-felling, avoiding biomass burning significantly reduces negative impacts on water resources.

Impact on Nutrient Loss

Tropical rainforests are particularly sensitive to site disturbance while their delicate structures, important for conserving nutrients, may be partially or completely destroyed during forestry operations, causing accelerated losses of nutrient. The magnitude of nutrient losses varies from undetectably small amounts in the case of a low intensity disturbance, to serious and permanent reduction in site nutrient capital as a result of a high intensity of disturbance

such as converting rainforest to pasture (Bruijnzeel, 1990). Nutrient removal occurs via biomass harvest, surface erosion and enhanced leaching to groundwater.

Losses of major nutrients following selective logging at Berembun catchment, increased by between 70% to more than 200%. Conversely, the supervised selective logging method showed moderate increases in solute losses, ranging from 13% for Na to 66% for nitrate (NO_3). Besides trapping sediment, buffer strips are also effective in filtering and reabsorbing nutrients before entering a water course (Brouwer, 1995).

An interesting study examining the effects of different methods of establishing the forest plantation on forests previously struck by fire, and forests that had been selectively logged, was conducted in Sabah, Malaysia (Malmer, 1993; Nykvist *et al.*, 1994). After two years of calibration, four of the six catchments were treated involving: (i) clearing of secondary vegetation, burning and planting (W1 and W2); (ii) clear-felling, crawler tractor extraction, burning and planting (W5), and (iii) clear-felling, manual extraction, no burning and planting (W4). The losses of major solutes were consistently higher from the normal practice treatment (W5) compared to manual site preparation with residuals unburned (W4). It is also interesting to note that, within the short time span (2.8 years) after treatment, the hydrologic losses of K and Fe had exceeded losses via stem wood even for the manually extracted and unburned catchment, W4.

Loss of nutrients on an annual basis may be small, but over a long term, the total loss can be substantial. Depending on the chemistry of the rainfall, the time span needed to compensate for nutrient losses following forest harvesting may range from 25 90 years for calcium (Ca), 20 35 years for magnesium (Mg) and 10 50 years for K (Zulkifli *et al.*, 1998). The slower recovery rate for Ca could be attributed to a much larger quantity of Ca for the formation of woody biomass compared to Mg and K. The implication of this study is that nutrient sustainability could be attained if forest logging is carried out over a 50-year rotation.

SUMMARY

The effects of forest logging on hydrological characteristics and water yield not only depend on several bio-physical factors; soil, geology and rainfall regime, but more importantly on the type of logging method used and the extent of forest cover removed. Although the effects of forest removal on hydrological regime and land cover are context-specific, several general inferences can be elicited from the examples reviewed, particularly on the cumulative effects and long-term changes. Cumulative effects of selective logging will be only manageable provided the logging cycle or rotation period is adequately long, and an effective enforcement of management procedures and conservation measures are fully enforced during logging operations. These may include an adherence to the RIL *reduced impact logging* approach, retention of buffer zone, proper planning of logging road and delineation of sensitive and protective zone for biodiversity conservation. Unless these are prescribed, there could be long-term changes in the water balances, geochemical cycles, sedimentation, local microclimate and carbon sequestration functions of forest cover.

Fugacity

Fugacity is a thermodynamic criterion of equilibrium for diffusion of mass within and between phases, and was developed by G N Lewis in 1901 as a surrogate for chemical potential. It can be regarded as the escaping or fleeing tendency of a chemical. It is usually represented by the symbol f and has units of pressure, namely pascals (Pa). For most environmental purposes, fugacity is equal to partial pressure. In many respects, fugacity is analogous to temperature as a criterion of heat equilibrium. It is proportional to concentration, and a proportionality constant (or Z value) is used to convert one to the other. These Z values depend on the properties of the chemical and the medium in which it is dissolved or sorbed. The use of fugacity is advantageous when assessing the fate of chemicals in multimedia environments because it standardizes the escaping pressure or chemical potential in diverse media such as air, water and biota so a uniform measure of chemical potential is applied to all media. Fugacity can be used to reveal the equilibrium status of media in contact, e.g., water and fish, and it can be used (in conjunction with appropriate transport rate parameters) to quantify the direction and rate of movement of a chemical, since a chemical will migrate or diffuse from media of high fugacity to those of low fugacity. The rate of chemical movement is also dependent on the fugacity gradient or difference between the two media, with larger fugacity gradients resulting in greater fluxes. It is thus analogous to Fourier s Law for heat conduction. Fugacity calculations are therefore invaluable when seeking to simulate and predict the rate of a chemical s movement within and between environmental media. Modeling results obtained using the fugacity system can be numerically identical to results from traditional concentration-based modeling systems that employ concentrations and partition coefficients, but the mathematics are usually simpler and more transparent in the fugacity system, especially when the system becomes more complex in terms of the number of compartments and processes. A wide variety of mass balance models based on fugacity principles is available.

For details of applications of fugacity to environmental simulations, see Mackay (2001) and Cowan *et al.* (1994).

G

Geoengineering: a Way to Stabilize Global Climate?

Gregg Marland

Oak Ridge National Laboratory, Oak Ridge, TN, USA

Many human activities are now carried out at such a large scale that they change the environment at regional to global scales. For example, burning fossil fuels releases greenhouse gases to the atmosphere, producing food and ber modi es the earth's surface, and building dams and irrigation systems alters the hydrologic cycle. Such activities have the goal of serving human needs or desires, but they are also, unintentionally, changing the global environment. Can we have large-scale activities deliberately designed to prevent the global environment from changing? Geoengineering suggests that that we might indeed do this on a very large scale.

The term *geoengineering* was first used in 1975 when Cesare Marchetti proposed a plan to collect the carbon dioxide discharged from coal-fired power plants in Europe and to inject it into the stream of subsurface water flowing out of the Mediterranean Sea into the Atlantic Ocean. This geoengineering scheme would put a large quantity of carbon dioxide into the deep waters of the Atlantic Ocean rather than into the atmosphere where it could cause global warming. That very large-scale engineering project would be designed to protect the climate from changes caused by excessive burning of fossil fuels. It is this very large scale and purposefulness that characterize and define geoengineering.

The US National Academy of Sciences used the term geoengineering in 1992 to characterize options to combat or counteract the effects of changes in atmospheric chemistry . They included proposals to plant large areas of trees to remove carbon dioxide from the atmosphere, approaches for increasing the ocean s absorption of carbon dioxide, and options for screening out some of the sunlight reaching the Earth. Counteracting the effect of carbon dioxide from fossil fuel burning could involve activities on the order of millions of km^2 of forests or screening out 2% of incoming solar radiation.

It has been suggested that fertilizing the ocean could increase the biological productivity of ocean waters and thus increase the rate at which carbon dioxide is drawn from the atmosphere. The carbon would then be carried into deep ocean waters where it would be stored for a very long time. Experiments to test the idea that some areas of the ocean are limited in the micronutrient iron have demonstrated that over small areas and short times, adding iron to the surface waters can cause an increase in biological productivity and an increase in carbon dioxide uptake. The long-term consequences of this sort of fertilization are not well understood (*see* Iron Cycle, Volume 2).

Several engineering ways of stabilizing the global climate have been proposed. Mathematical models of the climate system suggest that doubling the concentration of the greenhouse gas carbon dioxide would be as effective in warming the Earth, on average, as would a 2% increase in radiation input from the sun. Rather than decreasing the rate at which we burn fossil fuels, and release carbon dioxide, perhaps it would be possible to geoengineer a decrease in the radiation input from the sun and thus to counteract the effect of increasing carbon dioxide. Possibilities that have been suggested for reflecting away part of the incoming solar radiation include space mirrors, stratospheric dust, large numbers of reflective balloons, and sulfate aerosols in the atmosphere. A recent study suggests that a mesh of very fine aluminum wires in orbit around the earth could be designed to scatter solar radiation and thus to reduce solar input to the Earth by any desired amount. Sulfate aerosols from large volcanic eruptions have indeed resulted in large scale, temporary cooling of the Earth s surface.

Geoengineering might also be used to alter internal processes in the Earth s energy or hydrologic balances. But because of the close coupling of many processes on the Earth s surface is not well understood, it might be difficult to predict consequences and side-effects. Nevertheless,

there are a number of modifications that might be considered to manage the global environment. Modifications in the magnitude or distribution of cloudiness, the circulation of the oceans, the paths of hurricanes, or the area or brightness of ice have all been considered.

A major challenge of geoengineering generally is that we do not understand the Earth System well enough to know the full range of consequences of these activities. Might geoengineering result in positive outcomes in some places and at some times and negative outcomes in other places and at other times? Given this uncertainty, some have suggested that any geoengineering should be limited to activities that can be easily reversed or to activities that are within the range of natural variability.

The attraction of geoengineering is that some of the possibilities appear to be very inexpensive and easy to implement. Counteracting the effect of increasing concentrations of greenhouse gases might be much less expensive than trying to reduce emissions, and it would not depend on the behavior of large populations. It could be simply a matter of deciding what to do and how to share the costs. The issues of risk, responsibility, law, equity, and ethics are not as easy to assess and to deal with.

It has been suggested that geoengineering might provide the last-resort alternative if we are not able to otherwise prevent significant changes in the Earth s climate and we face major impacts on human welfare. Others worry that the mere possibility of geoengineering solutions could weaken our resolve to find other ways to avoid potential problems. Before any geoengineering scheme could be responsibly considered we would need to better understand the complex Earth System than we do now.

Geography

Geography is a discipline concerned with understanding the spatial dimensions of environmental and social processes. As defined by the editors of the recent review of advances among American geographers, it is the study and science of environmental and societal dynamics and society-environment interactions as they occur in and are conditioned by the real world (Gaile and Willmott, 2001).

While some geographic study focuses primarily on the distribution of human populations and economic and political activities, a wide variety of investigations have a major environmental emphasis. The latter include: studies of how human activities have altered the global environment; examination of changes in sectors of various natural systems; studies of people nature interactions and their consequences in major regions; and detailed examinations of smaller areas, encompassing either one sector or all sectors of the environment.

Geographers, beginning in 1864 and most recently in 1990, have made a series of reviews of the quantity and quality of human modifications in global land, water, and organic resources (Thomas, 1956; Turner *et al.*, 1990). These have been accompanied by more detailed analyses of changes in vegetation, land use, water management in selected regions, such as for arid and semi-arid lands.

Geographers contributed to appraisals of the possible natural and human consequences of changes in the global carbon cycle (Mather and Sdasyok, 1991; Bolin *et al.*, 1986), and they assessed the social implications of the hazards caused by extreme natural events in high-risk regions (Kasperson *et al.*, 1995; Burton *et al.*, 1993).

On a more local scale, they have carried out an immense number of detailed studies of how human actions have caused ecosystem change, and of how such change is, in turn, reflected in the pattern and quality of social activity.

With their emphasis upon integrated spatial analysis and upon human nature interactions, many geographic investigations are distinguished by their emphasis on regional scales, and by bringing together natural and social sciences.

Geomorphological Change for Urbanization and Industry

Ian Douglas
University of Manchester, Manchester, UK

Mining and urban development both involve removal of the natural vegetation cover and excavation of the topsoil and often much of the underlying weathered rock and bedrock layers. In new urban developments, small streams are often diverted into culverts or urban drains and minor depressions and valleys are lled in. Steep hillsides may be terraced into a series of home sites by cut and ll operations. Major rivers may be embanked and arti cially straightened. In extreme cases, as in Palma de Mallorca, Spain and Winnipeg, Canada, large new ood channels may be built around the urban center to divert ows away from the city. The new features, replacing the original landforms, are often designed to direct water away from the new developments more effectively, so producing off-site, downstream consequences.

Mining changes the land surface by creating pits and quarries, removing underground material and building up waste tips and tailings deposits. The largest excavations take up many square kilometers of the land surface, while waste tips formerly dominated the skylines of the old deep coal mining areas of Europe.

In extreme cases, the legacies of past mining activity still affect the morphology of major rivers as in the Sacramento River in California, US. Lakes in areas of former gravel working are prominent in the valleys of many rivers, for example, the Thames, Rhine and Seine Rivers in Europe. Removal of mineral resources and water from beneath the ground leads to subsidence creating new surface topographies and often new water bodies (Carbognin, 1985).

These changes in landform may often be individually small, but collectively they are the result of two of the main human drivers of global environmental change: increasing urban development and the mining and quarrying which supplies minerals for industry, and the construction materials required to build all the infrastructure, homes, of ces and factories of cities. Gradually, over the centuries, cities renew their built fabric, often using the demolished remains of earlier buildings as ll and foundations for the latest developments. Thus, the urban surface is gradually raised, again changing the form of the land surface in another way. An exception occurs in cities like Mexico City, where land subsidence is taking place.

In creating these new landforms and altering the workings of geomorphic processes, urbanization and mining have impacts far beyond their municipal or concession boundaries. Impacts of river systems, lakes, wetlands, estuaries, deltas and coastal zones may be particularly marked and persistent. Water quality in some rivers of the Pennines in northern England is still affected by drainage from Roman Pb workings. The impact of the transformation of some major rivers on New Guinea and Bougainville by the release of mine tailings and associated chemicals has been felt in offshore sheries in adjacent seas. Everywhere that rock or clay is extracted, that groundwater is pumped to the surface, coal mined or oil extracted, there are environmental consequences and landform changes. While modern mining technology and regulations can ensure successful restoration of changed landscapes and treatment of mining wastes, not all mines, quarries and wells in all localities in all countries adopt appropriate reclamation practices or have local regulations that are strictly enforced. Thus, the extraction of liquids and materials by mining and quarrying, and the modi cation of the land surface for urban development, will continue to contribute to environmental change long into the future.

LANDFORM CHANGE IN STEEPLANDS

Excavations in mountainous areas are usually highly visible and potentially dangerous. The problems experienced with the collapse of a tailings dam at the Freeport Copper Mine high in the Star Mountains of New Guinea illustrate how earthworks failures can affect hundreds of

kilometers of river channel downstream. Many important mineral resources can only be obtained by working in areas of high instability risk, and restoration after operations have ceased poses particularly difficult problems.

Mountain top removal and valley fill mining as practiced in West Virginia, US involves removing 100 400 m depth of rock from the crest of Appalachian mountain ridges to expose successive seams of coal. The overburden is dumped into adjacent valleys, covering streams and drainage lines, forming a valley fill. The largest individual mines occupy up to 40 km^2. Although now separated by green, forested, intact mountains, many will soon merge together as reclamation creates a new series of landforms of rolling topography, instead of steep ridge and valley relief (Kite and Skousen, 1999). Already, over 2% of the surface of West Virginia has been strip-mined since the 1977 Surface Mining Control and Reclamation Act. At the mine sites, huge draglines work continuously, leveling ridge crests in a matter of months. Instead of forests, many of the valley fills are converted to grassland for cattle grazing. Others are used for recreation as golf courses or football pitches, or for occasional large new shopping malls.

Similar topographic changes in mountain areas are caused by the development of new urban and resort areas in tropical steeplands. On the Main Range, east of Kuala Lumpur, Malaysia, at approximately 2000 m elevation, the Genting Highlands and Bukit Tinggi resort and residential area developments have led to the excavation of large areas of deeply weathered granite and the filling of many minor valleys. In an originally steep, rugged terrain, new golf courses and playing fields have been created, with the surrounding slopes modified into cut and fill terraces for the construction of houses and apartment buildings.

These huge earth-moving operations not only cause major environmental changes in themselves, but they have marked impacts on adjacent ecosystems, local stream flow hydrology and sediment loads, and slope stability. Water quality impacts can generally be controlled during active mining, but many coal seams cannot be mined without some residual acid mine drainage requiring treatment to protect nearby rivers. Valley fills and reclaimed strip mine and mountain top areas operate as artificial, porous areas through which rainwater penetrates to recharge groundwater bodies. Some of the infiltrated water emerges from the fill as highly acid seepages that often flow throughout dry periods when neighboring streams are extremely low. Sometimes the adjacent watercourses have alkalinities below 10 $mg\,l^{-1}$ and are unable to immediately neutralize inputs from reclaimed mine area springs with 1000 2000 $mg\,l^{-1}$ of acid. While reclamation activity offers real opportunities for habitat restoration and improvement, including the amelioration of fish stocks in rivers, some mining operations are unregulated and some companies fail to follow approved mining plans. Much mining in the 19th century had no regulation at all. The legacies of these past activities, and those of present poor practice, continue to affect fish and aquatic resources through erosion and sedimentation, dewatering of wetlands, diverting and channelizing of streams and contamination of surface water and aquifers with toxic chemicals. Some of these mining impacts are strictly geomorphological, altering processes and landforms in river channels and floodplains. Others permeate through food chains and change ecosystems, eventually having impacts on lakes and coastal seas.

SUBSIDENCE DUE TO MINING AND WITHDRAWAL OF FLUIDS

Land subsidence due to coal mining may be caused by the removal of the coal underground. Gravity and the weight of the overlying rock causes the layers of rock to shift and sink down into the void left by the removal of coal. Ultimately, this process can affect the surface, causing the ground to sag and crack and holes to form, which may severely damage or destroy buildings.

Occasionally, the impact of mining subsidence on the environment is catastrophic, destroying property and even leading to the loss of life. Most frequently however, such subsidence causes slight to severe structural damage. The geological situation, actual mining technique and type of mineral deposit determine the nature of the subsidence in any particular locality. Some mining methods result in contemporaneous subsidence, whereas, with others, subsidence may occur long after the mine workings have been abandoned. In the latter instance, it is more or less impossible to predict the effects or timing of subsidence. In the cases of gold mining in the Johannesburg area; room and pillar mining of coal in the Witbank Coalfield, South Africa; longwall mining of coal in the Ruhr district; mining of chalk in Suffolk, England and limestone in the English West Midlands, and solution mining of salt in Cheshire, England, the deposits concerned have often been worked for more than 100 years. Abandoned mines with unrecorded old workings not far below the surface may pose major problems when old mining and industrial areas are being redeveloped (Bell *et al.*, 2000).

Land use after deep mine-induced subsidence may create attractive opportunities. At Pennington Flash near Leigh, west of Manchester, England, subsidence following deep coal mining during the 19th century led to a water-filled depression, which developed around 1890. The depression quickly became a shallow lake that soon began to be used for recreation, particularly water sports such as sailing. After 1970, the area was developed into a country park, with restoration of adjacent derelict land and creation of wildlife refuges. The subsidence-affected area became fully integrated into a new phase of urban regeneration.

Like so many other water bodies, Pennington Flash has a high wildlife and biodiversity potential. While recognized at the local management level, the full potential of so many water bodies related to past extractive industries at the regional level, is often neglected. The full biodiversity and sustainability contribution of these legacies of extractive industries only occurs when they are seen as parts of systems of urban greenspace corridors and nodes within complex metropolitan areas. When thinking of the sustainability of cities and managing materials flows, the whole sequence, from natural land surface, through mining or quarrying, to possible landfilling, restoration and ultimate urban or greenspace uses, has to be considered. Material flows are thus intimately related to land uses and landform changes.

Removal of liquids has had particularly marked impacts on many cities. In the Houston, Texas, US areas, land subsidence first occurred in the early 1990s in areas of groundwater, oil and gas extraction. The subsidence continued throughout the 20th century, mainly because of further groundwater abstraction. The localities and extent of subsidence changed during that time. Before the early 1940s, removal of oil, gas and associated brine caused localized subsidence close to Houston. Nearer the coast, groundwater pumping for public supplies caused more than 40 cm of subsidence between 1906 and 1943 at Texas City. Further exploitation of the groundwater as the only source of supply led to subsidence affecting a large part of Houston, but mainly by less than 30 cm before 1943. The expansion of the petrochemical industry in the 30 years until 1973 put much greater pressure on groundwater resources with nearly 2 m of subsidence occurring along the ship canal between Bayport and Houston. By 1979, the most severely affected areas had been lowered by over 3 m, increasing their vulnerability to hurricanes and storm surges. The Brownwood subdivision of Baytown that had subsided by nearly 2.5 m was so inundated by a 3.5 m storm surge during hurricane Alicia in 1983 that all the homes in the area were abandoned. Now most of the subdivision is a swampy waterfowl habitat (Galloway *et al.*, 2000).

Since the late 1970s, subsidence has largely been arrested along the ship canal and in the Baytown-LaPorte and Pasadena areas, as the development of surface water supplies has allowed groundwater pumping to be reduced. However, as subsidence in the coastal area was stabilizing, subsidence farther inland, to the north and west of Houston, increased with the abstraction of freshwater from the Evangeline aquifer. More than 75 cm of subsidence occurred at Addicks, about 30 km west of Houston, between 1973 and 1996.

Groundwater exploitation has produced subsidence in many cities, among the most well known being Mexico City, Bangkok, Venice and Bologna. In Mexico City, groundwater withdrawal has produced 9 m of land subsidence in places. Most of this compaction has occurred in the uppermost 50 m below the land surface in two highly compressible silt clay beds 25 30 m and 5 10 m thick. From 1877 to 1952, the rate of surface lowering increased steadily, reaching a peak of 30 cm year^{-1} in 1948 1952. After 1952, subsidence slowed to about 5 cm year^{-1} in 1973. Since then, pumping of underground water in the central part of the city has been banned and further subsidence is not a serious problem (Carbognin, 1985).

In Bangkok, the rapid growth of the city outstretched the ability of the municipal authorities to provide the additional water needed, and many private boreholes were sunk. Local settlement of as much as 14 cm year^{-1} occurred, but because the complex sediments of the Chao Phya River deltaic plain had been disturbed and faulted by local earth tremors, differential lowering took place. As one sector of a street or one length of canal was lowered relative to its neighbors, drainage was disrupted and sewers were fractured. Despite the installation of new deep drains well below the zone of faulting-disrupted subsidence, parts of the city can still be inundated for many days during the heavy monsoon rains because of poor drainage.

Groundwater pumping has put the historic world heritage buildings of Venice at risk. Built at sea level on the lagoon, Venice has subsided some 22 cm since 1900. Most of that surface lowering occurred between 1950 and 1970. High water (aqua alta) has occurred more frequently since 1970. Whilst the people-induced subsidence is part of the problem, higher extreme sea levels related to global climate change may possibly be another factor.

In Bologna, groundwater exploitation has affected the historic core of the city, with lowering through differential sinking of foundations of up to 6 8 cm year^{-1}. These irregular changes pose major problems for building maintenance because of the stresses they place on structures. Many other historic Italian cities, including Ravenna, have similar concerns. Few cities where there is exploitation of groundwater, oil or natural brines beneath their buildings can avoid some degree of subsidence. The problem is perhaps most insidious in coastal areas, where the combination of subsidence with rising sea levels greatly increases the vulnerability to the effects of climate change.

QUARRYING AND LANDFORM CHANGE

Around Buxton in the Peak District of England, limestone quarries like Tunstead and Dove Holes have doubled the area of landforms changes by minerals extraction since 1920. Limestone remains the most important non-fuel mineral extracted in Britain, but its removal changes the landscape far more quickly than natural processes of weathering and erosion (Gunn and Gagen, 1989). The natural rate of erosion, or rock removal, by solutional processes

in the Peak District is approximately $70\,m^3\,km^{-2}\,year^{-1}$, equivalent to an annual loss of some 83 500 tons of limestone per year. The amount of limestone removed annually by quarrying rose from 2 million tons (Mt) per year in the period 1900 1920, to 5 Mt by 1949, to a peak of 22.5 Mt in 1973; since then it has fallen back to a more or less steady output of about $18\,Mt\,year^{-1}$. Extrapolating from these figures, the tonnage of limestone removed by human activity in just 100 years would equal the amount lost by natural solution processes over the whole 10 000 years of the Holocene (Gunn and Gagen, 1989).

Quarries can create two situations; voids in the ground or the removal of a topographic feature, such as a mountain top or a ridge of glacial gravels. In the latter case, a topographic feature has been removed by minerals extraction to create new surface landforms. Restoration usually involves grading and consolidating the surface before restoring the topsoil, which is usually removed and stockpiled prior to quarrying. Reshaping of landform remnants, perhaps to recreate something like the original form, may be part of the restoration.

With voids in the ground and conventional quarries, the options for restoration range from retaining the void and converting it to another use, perhaps as a lake or as a site for recreation or industry, to filling the hole and converting it to a landform akin to the original. Use of quarries as landfill sites is common enough and in some cases aggregate removal and landfilling take place one after the other as part of a single operation on one site. Containment systems, with liners of clay and strong plastics, gas and water abstraction pipes and regular daily covering of the waste, are needed to prevent impacts on surrounding areas. When filling is complete, the original land surface contours can be restored and the new surface returned to agriculture or some other land use. Where infilled quarries are later used for new buildings, problems of differential consolidation may be encountered. Several instances of settlement in former chalk pits filled decades ago occur every time there is a severe drought in southeastern England. Filling of old alluvial tin mine workings around Kuala Lumpur, Malaysia has occasionally produced similar problems. The alluvial tin is in a deposit overlying a buried limestone karstic area with many caverns in the bedrock. In a few places, the fill in the tin mine pits has been washed into the underlying karst cavities and buildings on the ground surface have suffered severe subsidence.

Restoration of the English Peak District quarries in an area of high scenic value has used blasting techniques to create more natural quarry faces that plants and animals can colonize more effectively (Cullen *et al.*, 1998; Gagen and Gunn, 1988). Careful landscape design on the floor of the quarry can create water bodies and a variety of habitats. Typical uses for quarry floors include construction, such as shopping malls, or industrial units, with protection of the untreated quarry faces for their geological conservation value.

Sometimes pumping of water from an operating quarry leads to landform change elsewhere, especially in karstic terrain. A large quarry near Rome, Georgia, US, was sunk about a kilometer from the campus of Berry College. Eventually, the quarry workings intersected the water table and water had to be pumped out of the quarry to enable working to continue. This pumping drew down the potentiometric surface in the surrounding rocks. In the limestone below the water table, water moved preferentially towards the quarry through passages enlarged by solution. The water entrained soil and weathered rock particles. This removal of material eventually caused a lowering of the ground surface and the appearance of a depression (sinkhole) at the surface. Many sinkholes appeared on the Berry College campus, some threatening buildings. The water of an artificial lake disappeared into one of the sinkholes (Kastning, 1998). The quarrying had introduced a phase of extraordinarily rapid karst landform development. Sinkhole development is a major problem in many karst areas undergoing urban development and water resource exploitation.

LANDSCAPE MODIFICATION BY AGGREGATE AND BRICK CLAY EXTRACTION

The excavation of building materials, such as brick- and tile-making clays, sand and gravel, which are low in value in relation to their bulk, has traditionally taken place close to the settlement where they are to be used. The Tuileries Gardens in Paris occupy the site of pits where clay was dug to make tiles (tuiles) for the city s roofs. The present Parisian park at Buttes-Chaumont was a belt of quarries and rubbish dumps until the mid-19th century. The 348 ha Central Park in New York was created in 1858 from an area of quarries, swamps, dumps and squatter housing. Valuable agricultural land is being lost around most Indian cities as farmers dig clay to sell to make bricks. Similar local clay extraction is seen around towns in Vietnam.

Both modern river floodplains and former river channels near cities are favored sources of sand and gravel. London has gravel workings along the present Thames floodplain and in the Vale of St Albans where the Thames flowed previously. Glasgow, on the other hand, has exploited gravels deposited under past glaciers. Floodplain gravel workings are operated as wet pits, and are usually left as water-filled areas when operations cease. Such sites are easily converted to lakes for water sports or wildlife refuges. However, the opportunities for successful conversion to recreational and environmental uses may be approaching their limit in some places. For example, the rapid increase in the area of former gravel pits near the head of the River Thames northwest of

Swindon, England has begun to outstretch the demand for water-based recreation and for managed wildlife refuges. Already the Cotswold Water Park provides large areas for water sports, while other pits are used for waterside caravan and weekend home parks or have been made into wildlife reserves. There is unlikely to be enough waste that can be hauled economically and be deposited safely, in gravels overlying limestone aquifers, to justify using these sites for landfill, which in any case is being discouraged by the UK landfill tax. In the Rhine Rift Valley south of Mannheim, Germany, a similar situation exists. The number of water-filled gravel pits has increased greatly since 1960. Here is an example of landform change that begins to sterilize land for future uses, just as the spread of cities over areas of economic clay or gravel resources, sterilizes that resource.

Demands for construction materials in many countries are so great that gravels are extracted directly from active river channels, for example around Beijing, China. In Java, Indonesia, the debris brought down channels by lahars from active volcanoes is exploited as construction material. In Kuwait, sand and gravel extraction often causes severe deflation and dust storms. As urban areas expand, the environmental changes due to construction materials extraction will become more intense and increasingly detrimental to adjacent ecosystems and watercourses, eventually affecting biogeochemical cycling.

IMPACTS OF AGGREGATE EXTRACTION ON ESTUARIES

In the Georges River in southern Sydney, England, three different local changes have affected the estuary since 1940: (a) a shift to a flood-dominated regime from a drought-dominated one in the late 1940s, which increased both water and sediment discharge (like urbanization) in a natural way; (b) sand dredging from the bed of the river in several upstream locations; and (c) dredging and quarrying of floodplain and terrace sediments at Liverpool and Chipping Norton. The shift to a flood-dominated regime:

(a) introduced more water and sediment naturally to the estuary from the 930 km^2 catchment after about 1948.

Sand dredging from the bed of the river created deep holes:

(b) that greatly increased the sub-tidal capacity, thereby increasing the flushing time to evacuate pollutants. The deep holes broke the continuity of the bed, which helped to promote erosion both upstream and downstream of the dredging sites. Additionally, the deep holes helped to undermine the banks in the dredged reaches. Thus, bank erosion became a problem.

Floodplain and terrace quarrying and dredging

(c) should have caused no problems to tidal dynamics, because they were essentially pits away from the river with a 20 m zone left along the banks. However, these banks failed with the passage of floods, and the ponds became connected with the tidal river, which created more problems. The tidal prism, which diminishes towards the upper part of the estuary, was greatly increased by having to fill the ponds on incoming tides and empty them on outgoing tides. This greater volume of water had to pass through the downstream channel more quickly, and thus also helped to promote bank erosion in the middle reaches of the tidal river, which had also been destabilized by dredging. The depth of the ponds dredged on the floodplains greatly increased the sub-tidal capacity at the upper end of the tidal channel. This helped to increase the flushing times by more than 100% (Bridgman *et al.*, 1995).

So the dynamics of the estuary were greatly modified by urbanization and sand dredging for aggregate. In the lower parts, both sub-tidal capacity and tidal prism volume were decreased, and in the upper parts, both were increased. The consequences of this were higher tidal current velocities that helped to promote bank instability and poorer flushing potential in an estuary where major sewerage works were built to discharge treated sewage into the river and the estuary.

COASTAL SUPERQUARRIES IN BRITAIN

The underestimation of demand for aggregates in the 1980s led to the exploitation of rock reserves in areas of high scenic value such as the Mendips and the Peak District National Park. Coastal superquarries provide a viable economic alternative to the further disturbance of such sensitive areas, capable of supplying much of the growth in demand in southeast England and possibly other regions. The first British coastal superquarry occupies a 250 ha estate at Glensanda near Fort William, producing 5 Mt of granite a year, with plans to export 15 Mt per year. The site has sufficient reserves for a hundred years or more. Most of Glensanda s output is, at present, exported to northern Europe and the US. A second site, the proposed Rodel quarry at the southern tip of Harris, has so far been refused planning permission and is the subject of an ongoing public enquiry. This is partly because of concerns over the impact of creating the largest man-made hole in Europe (2•4 • 1•6 km and 500 m deep), with a 1 km long deep sea loch. The effects of water discharges, noise and dust might affect the local environment and fisheries. A further geomorphic impact of the growth of superquarries

would be the effects on estuarine morphodynamics of the construction of up to 12 wharf and port facilities in the Thames and Medway estuaries to transfer the aggregates from ships to trucks. Each wharf site would need at least 5 ha of land, and access roads to accommodate at least 600 vehicle movements (including return trips) per day. The roads and wharves themselves would need more aggregates and other materials and so would add to pressure on resources. The scale of future geomorphic change by superquarry development probably depends on acceptance or rejection of the argument that six superquarries on the Scottish coast are preferable to 45 large inland quarries in the Mendips, Leicestershire or the Peak District, or even 450 sand and gravel pits in south-east England. Promotion of the use of secondary, recycled material would lessen the geomorphic impact of increasing demand for aggregates.

These examples of the impacts of aggregate extraction show that the impacts of simple needs for materials for housing and shelter collectively build up into major environmental modifications.

LAND RECLAMATION BY DUMPING AND INFILLING

Many cities around the world have had to seek to create landforms to house their activities. New airports have been built on artificial islands or peninsulas at Chek Lap Kok Airport, Hong Kong and Kansai International Airport in Osaka Bay, Japan. Runways have been extended into the sea at Sydney and Beirut. The quantities of material involved are large. 102.1 Mm^3 of material were moved to build Chek Lap Kok Airport. Construction of the Airport Island Seawall for the new Central Japan International Airport offshore of Tokoname City, Aichi Prefecture will involve moving some 13 Mm^3 of material.

Other cities have infilled coastal wetlands and reclaimed sectors of their foreshore. At Kota Kinabalu, the capital of Sabah, Malaysian Borneo, filling of the mangrove swamps behind coastal beach ridges for urban development removed the areas where floodwaters used to spread, causing parts of the town to be flooded during storms. In addition, large areas of the foreshore have been reclaimed, both for expansion of the city center and for tourist developments, including a marina and golf course. The disturbance during filling created high suspended sediment concentrations in the sea between the city and the offshore coral reef-fringed islands of the Tuanku Abdul Rahman National Park. The potential for damage to the reefs, themselves a major tourist attraction, is high. Such deliberate geomorphic changes always have some unwanted side effects.

A particularly fine example of an artificial coastal landform is provided by the Leslie Street Spit, which was created by depositing hundreds of thousands of tons of construction waste, large rubble, and other waste materials into Lake Ontario. The Spit just off Toronto, Canada has three cells each designed as a confined disposal facility for the dumping of dredged material. Cell 1 covers 8.2 ha of water area and was filled to capacity with 365 441 m^3 of dredged material by the end of 1987. At that point, disposal operations began in Cell 2, which covers 9.3 ha of water area and has an estimated capacity of 530 000 m^3. Covering an area of 32.1 ha, Cell 3 is the largest of the three cells and has an estimated capacity of 2.2 Mm^3. The total of material moved to make the Spit thus exceeds 3 Mm^3.

The Leslie Street Spit has little relief, and is covered with thin layers of vegetation. Some areas at the outer edge of the spit are in the stage of developing primary beaches. Small plants are invading the rubble and construction debris. However, around Cell 3 and the southern end of the spit, where dumping remains active, no natural beach development is occurring.

The Leslie Street Spit consists primarily of silt, fine sand and clay, the silt portion of the sediment accounts for 47 59% of the sediments, sand 18 34% and clay from 14 23%. The sediments are generally well consolidated with relatively few voids through which contaminated water could penetrate. The water around the Spit contains few contaminants, but some of the dumped material does not meet Canadian open water disposal criteria, although it is within the sediment guidelines for confined disposal. Concentrations of polychlorinated biphenyls and metals in the adjacent lake waters meet the requirements under the Canadian decommissioning guidelines for parkland, residential and agricultural soils. Concentrations of pesticides are also comparable to other waterfront locations in Toronto. These results demonstrate that the disposal cells are effective in their containment of the dredged material and that contaminants from the cells are not leaching into Lake Ontario. This Canadian example illustrates that, with adequate care and attention, surplus material can be dumped in a creative way to create new geomorphic features that create new land use or wildlife conservation opportunities. They are always a contribution to environmental change.

It is to be noted that an active citizens group FRIENDS OF THE SPIT has been active over the years to ensure that the Spit is developed as a conservation area, particularly as a natural site for studying ecological succession. See http://www.interlog.com/• fos/.

RE-USE OF DERELICT LAND (BROWNFIELD SITES)

In the old industrial areas of the world, the regeneration of derelict land is constantly taking place and much brownfield land has been re-used. Half of the new urban development in England has been taking place on land that had

Table 1 Land Justifying Reclamation in Greater Manchester

Year	Hectares of derelict land
1974	3186
1982	4025
1988	2734
1993	3227
1999	3217

previous urban, but not necessarily industrial uses. Much derelict land is highly concentrated in old coal-mining and heavy industry districts. For example, in 1990, the Nord-Pas de Calais region of France, with only 2.3% of the total area of France, had around 12 000 ha of derelict land, more than half the national total. In England, there were 39 600 ha of derelict land in 1995, of which some 27 000 were considered to be contaminated (Kivell, 1999). In 1999, Greater Manchester alone still had some 3217 ha waiting to be tackled (Table 1). Derelict land is being created almost as quickly as it is restored. Stricter regulations are requiring more effective removal of toxic chemicals (*see* Contaminated Lands and Sediments: Chemical Time Bombs?, Volume 3). Many sites are reclaimed for further industrial use or for new retail parks and shopping malls, but major political commitments are being made to endeavor to see that the majority of the need for new homes in countries like the UK is met by building on brownfield sites. Each restoration involves considerable demolition, filling and landscaping, so that the landform of the restored site may differ considerably from that of the original.

Yet, innovative initiatives are now starting to tackle the regeneration of derelict land, particularly closed landfill sites where risks of contamination may remain. Greater Manchester alone has over 900 closed landfill sites The Red Rose Forest, one of 12 semi-government community forest organizations in England and Wales is examining the potential of these sites for re-development as community woodland. Monitoring of 11 woodland initiatives on closed landfill sites in the region has demonstrated mean survival rate of over 80% for all tree species in the first year. The potential for using soil-making material derived from municipal waste for the beneficial regeneration of 23 closed landfill sites was being explored in 2000 2001. Thus, eventually derelict brownfield sites could be restored to new landforms supporting forest ecosystems capable of sequestering some of the carbon dioxide generated by activities on other restored sites.

CONCLUSION

The total area of actively operated, re-used or abandoned mineral workings is relatively small. For example, active mineral workings or former workings not yet reclaimed, and including land used for associated buildings and machinery, occupy 60 043 ha, 0.46% of all land in England. However, the associated landform changes are marked and have impacts well beyond the areas they occupy.

Good examples of landform restoration and control of mine effluents can be found. However, not all countries and local authorities can afford to restore areas of mining and quarrying or to regulate the impacts of the chemicals used in mineral ore processing or added to the environment by mine drainage. The geomorphic changes and associated environmental impacts caused by mining and urbanization will be of increasing environmental significance as more and more of the world s people live in towns and cities.

Geomorphological Change: Landscape Modification for Recreation

Gerda K Priestley
Universitat Autònoma de Barcelona, Barcelona, Spain

Recreational activities form an integral part of everyday life, especially in advanced, predominantly urban societies. The majority of these activities may be classi ed as sports. Most are urban-based; many occupy small extensions of land; some even take place indoors. The resulting impacts of these activities thus form an integral part of the urban matrix. There are, however, certain outdoor activities, which require the use of large extensions of land, which are normally located in rural areas or on the rural-urban fringe. Some of these outdoor activities generate considerable impacts. Figure 1 provides an overview of the impacts of a number of popular sports, of which golf and skiing are clearly those which generate the most signi cant impacts, although the nature of the corresponding transformations varies considerably.

GOLF

Golf can, in fact, be played on any large open space or field, the only essential requirement being a small hole into which a ball must be dropped. Many 18-hole regulation golf courses require a minimum surface area of 30 ha, and they have been specifically designed for the purpose. There are almost 30 000 regulation golf courses in the world and over 50 million people playing this sport. Golf courses may constitute highly positive elements in the landscape, especially where they fulfill the function of green, open spaces in the suburban expansion of large cities, as is the case in London; or where the presence of water surfaces leads to the enrichment of the flora and fauna.

Nevertheless, attention usually focuses on the negative impacts associated with the construction of golf courses, the most important of which are:

- destruction or modification of the top layers of soil as a result of disturbance during course construction. This can, in some cases, also cause soil erosion;
- excessive demand for water for irrigation when located in regions with a rainfall and humidity deficit;
- loss of water through evaporation from artificial lakes;
- application of chemical fertilizers and other products for the treatment of grass, which can lead to the contamination of aquifers;
- disturbance and modification of adjacent ecosystems, plant communities and fauna.

Obviously the degree of impact varies from one course to another. Two key factors are fundamental in determining such impacts: natural conditions (climate and the physical characteristics of the location of the course) and course design. Golf was originally played in humid regions where

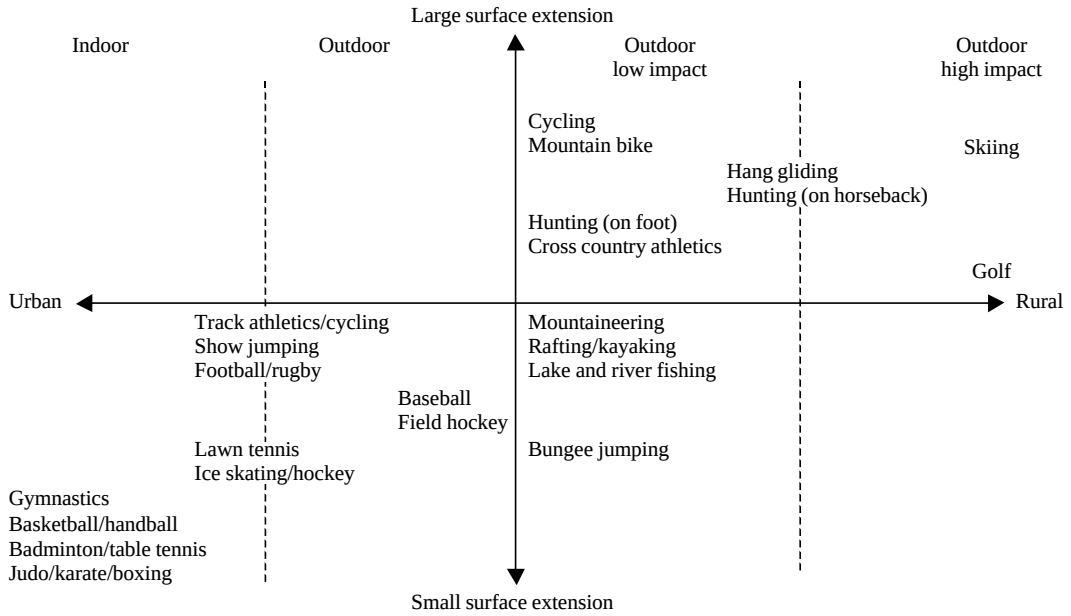

Figure 1 Sports activities: location, extension and impact. Some spectator sports like football produce major secondary impacts, e.g., the provision of huge parking facilities

grass grew naturally. Modern irrigation techniques have permitted its expansion to areas with drier climates, which have gained in popularity mainly as tourism destinations. It is in these regions where the negative impacts of golf courses are potentially most important, as large quantities of chemical products are often required to stimulate the growth of grass, or to counteract the reaction to recycled waste water, which is used for irrigation purposes in the absence of abundant rainfall or fresh water in the aquifers.

The physical characteristics of the location of golf courses (the site chosen) also influence the resulting degree of impact. Measures taken during the construction of a new golf course, such as the remodeling of the landscape, the removal of natural vegetation, or the construction of artificial lakes, can disturb the ecological balance of the environment. Course design is an important factor, not only in determining the impact of these initial measures, but also the recurring impact of subsequent course maintenance. The international trend in course design is towards the emulation of famous North American courses, of which the perfectly landscaped and manicured, world famous Augusta National course in Georgia is without equal. The traditional Scottish natural links (i.e., coastal dunes) courses, such as The Old Course at St. Andrew s, are seldom used as a model for new designs. As a result, most of the courses constructed during the golf boom of the last 20 years include elements that do not exist in the surrounding natural environment. Apart from the basic requirement of a relatively large extension of well cared for grass, the elements most commonly found are artificial lakes and non-native tree and shrub species.

With the prospect of the occurrence of global warming during the 21st century, increasing attention will have to be paid to environmental impacts in the design and management of golf courses. It will be fundamental to adapt course design to the natural environment, and to implement management measures that permit the more efficient use of water, such as intelligent irrigation systems, and the mandatory use of recycled waste water.

SKIING

The impacts of winter sports, basically downhill and cross-country skiing, but also more recent forms, such as snowboarding, can to some extent be compared with those of coastal tourism. Downhill, and to a lesser extent, cross-country, skiing can be considered the counterpart of mass sun/sand/sea tourism on account of its spatial concentration, accompanying construction of hotel and apartment accommodation, and mass but seasonal demand. There are, however, some notable differences between the two forms of tourism: there are fewer areas suitable for winter sports and, as most are located in mountain chains, access is usually more difficult and airports far removed from the resorts. As a result, traffic congestion is common.

The principal permanent impacts of winter sports, which also correspond basically to three different altitude zones, are:

- the presence of access roads, often several lanes wide, totally out of place with respect to the surrounding landscape;
- the accompanying residential and hotel development (in the Alps alone, there are over three million beds available);
- infrastructures associated with the practice of the sport: cable ways, ski lifts and ski jumps.

Other impacts exist that are visible only when snow melts in the warm season and when the tourism demand in many ski resorts remains high as a result of the scenic beauty of such mountainous areas. It is then that the devastating effects of the careless exploitation of natural resources becomes apparent. These include, principally, the clearing of woodland and protective forests; the opening-up of glaciers for winter sports; and land scouring and damage to soils, especially on the lower, beginner ski slopes and access areas to ski lifts. The negative impacts are not limited to such relatively localized elements. Land speculation, as a result of the demand for accommodation at, and even on, ski slopes, has led to the expansion of settlement in ecologically sensitive zones. The accompanying abandonment of agriculture and, consequently, the lack of attention to preserving the landscape, have impaired the natural beauty of the landscape. Furthermore, traditional architectural styles have frequently been replaced by imported ones, requiring damaging construction modes. Impacts are not, however, limited to visual aspects, for the consequences of elemental forces have also intensified. Drainage networks have been disrupted, with the consequent increase in the risk of soil erosion, landslides, floods and avalanches.

As global warming progresses, the future of skiing is somewhat unpredictable, but, certainly, the existing resorts will attempt to maintain demand by applying modern technology to generate snow artificially. New resorts may eventually develop in locations nearer the Poles or at higher elevations, hopefully applying measures to reduce environmetal impacts.

Green Revolution

Kenneth A Dahlberg
Western Michigan University, Kalamazoo, MI, USA

The Green Revolution is the name given to a package of fertilizers, pesticides, irrigation, and high-yielding varieties (HYVs) of crop seeds developed in the 1940s speci cally for use outside the temperate zones. The new seed breeding techniques developed in the 1930s for temperate-zone agriculture were used to modify local disease-resistant seed varieties in the developing countries to make them more productive, less sensitive to variations in day length in order to facilitate their wide dissemination throughout different climatic zones, and in the case of rice, to make them earlier maturing to facilitate double cropping. The hope of its promoters, initially led by the Rockefeller Foundation, was that by increasing food production in the developing countries and thereby - it was assumed - alleviating hunger, the Green Revolution would prevent red (i.e., communist) revolutions. By the 1960s, this package was aggressively being spread throughout the developing world by a new network of international research centers and aid programs, with wheat, rice, and maize being the leading crops involved.

A second phase of the Green Revolution emerged in the mid-1980s when new genetic engineering techniques, combined with expanded intellectual property rights (patents) and free trade agreements, gave transnational corporations a much greater ability to shape not only agricultural policies worldwide, but the whole structure of the food system. This power has raised fundamental questions about the ability of democratic societies to set standards for food safety to protect their citizens or to enable them to choose foods produced in environmentally sustainable ways and/or socially just ways which provide farmers and farm workers reasonable incomes and working conditions.

The signi cance of the Green Revolution in terms of global environmental change is that its rst phase extended industrial agriculture in most parts of the world down to the village level, thus dramatically increasing global fossil fuel demands for this highly energy inef cient and environmentally and socially destructive mode of agricultural production. Other global environmental impacts from industrial agriculture include soil erosion, salinization and water logging from irrigation, surface and groundwater contamination from pesticides and fertilizers, and the loss of cultural and biological diversity. The second phase is accelerating these unsustainable trends and is creating a global industrial food system that is highly fossil fuel intensive not only in the production sector, but in processing and distribution - where the average food item is more highly processed, more heavily packaged, and transported increasing distances. By contributing to increasing economic and social inequities at both national and international levels, this system also increases the risks of social instability. The need for more sustainable and socially just food and agricultural systems is clear.

The development of modern industrial agriculture can be traced to an increasing interaction between changes in agriculture and the development of modern science and technology. While the Arabs were the first to practice a science-based agriculture, their knowledge and technologies were ignored or lost as they were driven out of Europe. The values emerging from the Reformation and Renaissance helped lay the foundations for industrial institutions and technologies. The discovery of the New World generated intense interest in new plants and animals (as well as peoples) and the botanic gardens then established reflected an awareness of their strategic economic importance. While there was a very important agricultural revolution which preceded and made possible the industrial revolution, the latter, with its strong urban, industrial, and technological foci, soon led to a general neglect of rural, agricultural, natural, and informal systems. The new and formalized industrial organizations soon became a male preserve, while informal and natural systems became more associated with women and female role models.

It was, however, these natural, agricultural, and informal systems which provided the resources upon which industrialism was built. Over time they have been progressively incorporated into the formal systems of industrialism through the enclosure of land, forests, fisheries, and other common property resources. Typically this was done by placing lower level groups and environments under the

jurisdiction and control of higher level organizations state or corporate.

One of the greatest areas of difference between agriculture and the industrial model lies in the great contextual variability of agriculture where climate, weather, soil, topographic, resource, cultural, social, and institutional variations all profoundly affect its viability as contrasted to industry, where the universalism and rationalism of modern science and technology promote blueprint approaches whereby local variation is fitted to the design, often in a procrustean manner. It is only in the 20th century that there has been the capacity to start systematically applying the industrial model to agriculture.

Thus, while the early practice-based agricultural revolution and the social and political changes associated with the enclosure of the commons had profound societal impacts, they were not science and technology driven. Using modern modes of analysis, such as input/output and rates of growth in productivity, to determine when the most radical changes occurred historically, Grigg (1984) concludes that:

> It seems that European agricultural change was evolutionary rather than revolutionary until this century. It is the period since the 1930s that merits the title [of agricultural revolution].

This modern farming revolution in Europe had parallels in both the Union of Soviet Socialist Republics (USSR) and the United States. In the USSR, the destruction of peasant farming and its replacement with state-owned and managed factory farms offered a new variant on the industrial model of agriculture, one where the standardization of organizational and management practices predominated. In the United States, a standardized production package gradually emerged, based on synthetic fertilizers, pesticides, irrigation, and hybrid seeds. The success of this production package in increasing yields laid the groundwork for the Green Revolution where the underlying idea was that it should be transferred to non-temperate zone countries and colonies.

The Green Revolution has been the subject of much controversy from its beginnings (Karim, 1986). In what can be seen as the first phase of its development roughly from the 1940s to the mid-1980s there were dramatic increases in *per capita* food production in Asia, modest increases in Latin America, but serious declines in Africa. Proponents attributed the gains largely to the Green Revolution, while critics argued that the longer-term environmental, social, and equity costs of these gains were not included in the balance sheet. Some of these concerns were addressed as a network of international agricultural research centers was created. The second phase, which is still ongoing, has involved the increasing incorporation of agriculture into a global food production, processing, and trading system based upon genetic engineering, intellectual property rights, free trade, and the increasing concentration of large corporate power at both national and international levels. This larger global food system is supported by governments and dominated by large transnational corporations.

The first phase of the Green Revolution (1940s mid-1980s) can be understood as the increasingly systematic export of temperate zone industrial agriculture to the developing world which is largely non-temperate zone. Precursors from the 16th century onwards included tropical crops such as sugar cane, indigo, coffee, tea, groundnuts, and rubber, which were developed in the colonies along industrial lines. That is, large-scale production facilities were created called plantations rather than factories often displacing small-scale local subsistence farmers through land expropriation. Labor was also organized in an industrial manner, first with slaves, and later with highly exploited workers. The scale, structure, and management of these plantations all reflected Western industrial approaches and notions of economic rationality. Their direct linkage with the factories and markets of metropolitan countries was a major factor in creating the dual economy of most colonies.

Precursors to the Green Revolution in the white settler colonies involved the immigrants importing their familiar temperate zone crops, animals, and cultivation techniques (Crosby, 1986), plus Western agricultural research approaches (Dahlberg, 1979). Settlers and colonial administrators believed in the superiority of their crops and practices, just as they believed more generally that Western culture, religion, and economic and political institutions were superior, thus justifying the use of the West s genuinely superior military technologies to impose them.

Important as these precursors were as both precedents and indicators of deep-seated Western assumptions about agriculture, their overall impact on the vast majority of rural subsistence peasants, nomads, and villagers was very small. The foundations for the later rapid expansion of the Green Revolution lay more in the creation of centralized colonial infrastructures and administrative control systems which enabled relatively small Westernized enclaves symbolized by Western-style cities to penetrate the colonies and extract their resources.

In the early 1940s, the Rockefeller Foundation, motivated in part by a fear of rising global hunger seen to be caused by rising populations sent a team of plant breeders to Mexico to explore how to increase agricultural production. The Foundation officials and plant breeders involved worked from the widely held assumptions that increased agricultural production would reduce hunger and that technologies are neutral and can be transferred with only minor local adaptations. Because these assumptions serve a number of powerful vested interests, both remain strong even today, in spite of convincing evidence to the contrary (Sen, 1981; Dahlberg, 1989). Critics at the time, notably geographer Carl Sauer, questioned the Foundation s approach, arguing presciently that the production package of HYVs,

synthetic fertilizers, pesticides, and irrigation would favor those already better-off farmers and regions with access to irrigation more than the large majority of dryland peasant farmers located in the more arid regions of Mexico.

Had the Rockefeller Foundation asked what was required to improve the rural welfare of most Mexican peasants, the logical answer would have led them to an interdisciplinary effort to deal with the challenges of dryland farming something the earlier Cardenas government in Mexico (1935 1941) had worked on. Eventually responding in the mid-1960s to criticisms that its hybrid maize varieties were benefiting only better off irrigated areas, the Rockefeller Foundation did create a regional project, the Plan Puebla, in a dryland region. Reviews of this project showed that traditional improved open-pollinated varieties of maize did almost as well under dryland conditions as high-yielding hybrids and had the additional advantage that the farmer could save seed for next year s crop and not have to buy hybrid seed. These studies also showed that in increasing yields, what was most important was to take careful account of a farm s elevation, its soil morphology and moisture, planting dates, and to provide effective credit for small farmers. The clear implication was that the transferable production package was maladaptive and that a farming systems approach to rural development adapted to specific regions was required (Redclift, 1983).

The gradual institutionalization of the Green Revolution was based on the impressive increases in yields the US plant breeders and their Mexican apprentices had achieved. While the original mandate was to explore all major food crops, increasing production proved easiest with wheat, then maize, and more difficult with beans with the former two crops becoming the focus of research. Because a strategy of developing hybrids for wheat was not used, the HYVs developed in the 1950s could be disseminated rapidly throughout the Asian Subcontinent in the mid-1960s when there was a fear of looming malnutrition and starvation (Borgstrom, 1967). The pioneering leader in this wheat research, Norman Borlaug, was awarded the 1970 Nobel Peace Prize for his work (Borlaug, 1997).

With maize, the strategy of focusing on hybrids meant increased production only in those few, already fairly well-off regions where most of the trappings of industrial agriculture were already present, i.e., irrigation, mechanization, distribution networks for seeds, fertilizers, and pesticides, credit, extension services, and markets. As noted above, in dryland conditions, hybrid maize was only slightly more productive and generally more costly. Work on beans again showed the dominance of the production paradigm, where it was not until 1949 that tests were finally made to determine the relative protein and tryptophan content of the improved varieties of this basic dietary staple. While more productive, the improved varieties had less protein and tryptophan. Since then, there have been attempts to breed more usable protein into HYVs but they have not been very successful.

By the 1950s, the Rockefeller program had been expanded to include other Latin American countries and other food crops, especially the potato. Work was also begun in India on maize, sorghum, and millets and in the Philippines on rice. In 1959, the International Rice Research Institute (IRRI) was chartered, with funding coming from both the Rockefeller and Ford Foundations. By 1960, concerns over population growth and possible famines led to a massive Ford Foundation program in India to increase production not only though a package of inputs (HYVs, fertilizers, and pesticides), but accompanying supports (tools, credit, price incentives, and markets). With a 1966 pledge of $1 million, the Rockefeller Foundation backed the transformation of the research institute it had long-supported in Mexico into CIMMYT the Spanish acronym for the International Maize and Wheat Improvement Center. IRRI and CIMMYT became the first two of what has now become an international network of sixteen agricultural research centers known as the *Consultative Group on International Agricultural Research* (CGIAR). The CGIAR is funded by the World Bank and a consortium of other United Nations (UN) agencies, national aid programs, and private foundations. Its budget in 2000 was US$331 million.

The CGIAR has research centers devoted not only to work on various crops (wheat, maize, rice, potatoes), but to livestock, cropping problems in specific climatic zones (tropical, semi-arid, and dry), forestry, agroforestry, living aquatic resources, water management, food policy, and support of national agricultural research programs. The gradual growth of this network, both in scope and diversity, represents an acknowledgment by the international community of the importance of agriculture. It also represents partial acknowledgment by the agricultural establishment of criticisms of the system and the Green Revolution over the years.

These included social, economic, environmental, and gender critiques. A major debate about the nature and direction of rural development was sparked by the development by IRRI of hybrid varieties of rice. The UN Research Institute on Social Development issued a series of reports documenting the Green Revolution s unequal social and economic impacts and their risks. The 1970s energy crisis led to a series of academic studies that highlighted the great energy inefficiencies of industrial agriculture, with the US food system requiring roughly 10 energy calories to deliver 1 food calorie on people s plates (Steinhart and Steinhart, 1974). Environmentalists criticized the high environmental costs of industrial agriculture at home and abroad. Particular emphasis was placed upon the global loss of cultural and biological diversity as well as such local and regional impacts as soil erosion, salinization and water logging from irrigation, surface and groundwater contamination from pesticides and fertilizers, and the loss

of small towns. Beginning in the 1980s, women s groups around the world began an ongoing critique of the huge gender biases found in agricultural research priorities and in the staffing of agricultural ministries, universities, and extension programs worldwide.

In addition to these issues, there were systemic critiques and searches for alternatives. Systemic critiques stressed the ways in which industrial models whether capitalist or socialist focused on production and generally ignored its many social, political, and environmental externalities. The inadequacies of neo-classical economics were shown through assessments of the real-world costs of *industrial agriculture*. These include the health costs to farm workers, farmers, and consumers; the social costs involved in the loss of rural towns and communities, the national and international economic disparities generated through industrial agriculture, the depletion of non-renewable resources, the degradation of renewable resources, and especially the losses of cultural and biological diversity (Dahlberg, 1986; Shiva, 1991).

Others sought out alternatives to industrial agriculture, some existing and some new. Organic farming and biodynamic agriculture, inspired by traditional Asian practices, were brought and adapted to the temperate zones in the 1920s. Newer approaches like *agroecology*, and *regenerative agriculture* and *regenerative food systems* emerged in the environmental and post-oil embargo era, drawing heavily upon ecological and systems theories. Agroecology includes two approaches. One analyzes traditional and indigenous Third World agricultural systems in ecological terms to understand how the demonstrated sustainability of many has been achieved through social, economic, and technological adaptations to the local environment and culture. It focuses primarily on farm and village level systems, but includes a strong concern for land tenure and social justice issues (Altieri, 1995). The other, *permaculture*, is an ecological design approach which applies ecological principles to specific contexts.

Regenerative agriculture and regenerative food systems use an approach based on ecological hierarchy theory. They seek to understand how to regenerate over multiple generations not only local cropping systems and farm families, but rural communities, landscapes, and regions. This approach includes not only production-related matters (e.g., agriculture), but the total food system from production, food processing, preservation, and distribution to preparation, use, recycling, and disposal. Both alternatives also examine the larger setting of agriculture, including traditional issues of social justice, land reform, and rural development as well as newer issues of free trade, aid, technology transfer, corporate power and the increasing disparities between rich and poor countries. Policies needed nationally to spread the more sustainable farming systems developed have also been analyzed (Conway and Barbier, 1990).

Critiques of these and alternative approaches reviewed all agree on one point: that industrial agriculture is unsustainable over the longer term. As the US farm crises of the 1980s persuaded many groups and finally the US agricultural establishment of the need for changes in agriculture, sustainability became the most widely accepted label acknowledging this need. As a not very descriptive term, it, of course, raises its own basic questions: What or who is to be sustained? How? For how long? And at what cost? As indicated, answers from the various alternative approaches include everything from sustaining farm fields, soils, aquifers, and habitats to peasant and farm families and their rural villages and communities to crop germplasm and cultural and biological diversity from the local to the global level. It is also recognized that all this will have to take place within larger frameworks of sustainable societies and a sustainable international system. Throughout, one sees a clear difference between the great emphasis of alternative approaches on context as compared to the standardized blueprint approaches of industrial agriculture.

The second phase of the Green Revolution started emerging in the mid-1980s. International debates over sustainable development, biodiversity protection, and global warming raised questions about the sustainability of industrial society in general, not just industrial agriculture. New technologies and legal and trade doctrines have also shaped this second phase. The development and increasing importance of genetic engineering combined with the ability of corporations to use new intellectual property rights to patent or otherwise own genetically-modified plants, livestock, and other agricultural or food-related organisms has led to a new political economy of food and agriculture. This has been extended to the international arena through new liberalized rules on free trade and their institutionalization in regional trade agreements and the World Trade Organization.

Many key questions have emerged in this dynamically changing setting.

- Do states have sovereignty over the genetic resources found in their country?
- Can they restrict access to or the export of genetic resources?
- Are they entitled to royalties on their genetic resources when corporations genetically modify and then patent them?
- What about the rights of indigenous peoples?
- Can the labeling of genetically modified foods or products be required?
- Can national standards and/or labeling systems be negated by regional and/or international trade agreements?
- Can labeling go beyond the health and safety of a food product to include its place of origin and/or the manner in which it was produced and/or processed (through organic methods; as kosher food; or without the use of child labor).

What appears to be occurring is a transformation of industrial agriculture into a global industrial food system. The main players in the various traditional sectors agriculture, processing, distribution, retailing are beginning to realize this, but are having difficulty in making organizational adjustments.

The response of the agricultural establishment to this emerging global food system has been mixed. It has acknowledged and sought to address many of the specific environmental criticisms emerging from the sustainable development, biodiversity, and global warming debates. As noted, the CGIAR network has broadened its scope. The new President of the Rockefeller Foundation, Gordon Conway, is promoting a doubly green revolution which seeks rural development of the world s poorest regions though sustainable farming systems developed with full farmer participation (Conway, 1998). Another long-term leader argues for an evergreening revolution (Swaminathan, 1996). These responses, however, still focus on agriculture as a largely rural sector and neglect the significant potential of urban agriculture and local food systems (United Nations Development Program, 1996). Beyond that, they don t address the profound organizational and political changes required to achieve their proposed reforms. For example, the development of agricultural biotechnologies still assumed to be neutral has reinforced the functional specialization and production orientation of most existing organizations, making reform even more difficult, especially given the increasing power of private actors with vested interests in current systems and structures.

Particularly crucial is the question of how governments, at whatever level, can regulate and control such developments for the long-term public good. Governments too are structured along functionally specialized lines, which make it difficult for them to address systemic issues. They are hampered in getting advice by similarly fragmented academic traditions. Even in research areas like the environment and global warming, where there has been interdisciplinary work within the natural sciences, there is very little involvement of the social sciences or humanities. Thus, the crucial role of institutions and organizations as well as values and culture in shaping changes in human behavior is neglected (Bennett and Dahlberg, 1990).

Alternative efforts to bridge and integrate these issues include work on ecological economics and sustainable food systems. Ecological economics argues that conventional economics needs to be reconceptualized in terms of the basic principles of thermodynamics and ecology. Sustainable and regenerative food system analysts argue that the fundamental shift in evaluative criteria between industrial and regenerative systems is from production/productivity to health. Food systems thus must be evaluated in terms of their health over multiple generations. The importance of healthy local food systems is stressed since they can not only greatly reduce fossil fuel use, but can be a significant part of sustainable local and/or regional development.

Since agriculture and food systems represent one, if not the major interface between natural and social systems, they are key areas for seeking to reduce the risks of global warming and other types of global change. Major land-use issues, the quality and availability of fresh water, public health, and issues of basic equity and democracy are involved. While there are major conceptual, technological, and organizational barriers to developing sustainable food systems, emerging paradigms and social movements are challenging the traditional industrial paradigm. These need to be translated into political, professional, and personal strategies and actions that will help to overcome and transform the power and inertia of industrial structures and interests. Citizens, professionals, corporations, and governments have to be persuaded that their longer-term interest lies in developing more sustainable systems. They will have to be encouraged to make difficult, but necessary changes in organizational structures and in their ways of life. They must come to realize that just as healthy food is required to nourish the body, healthy food systems are an essential part of sustaining the biosphere.

Greenhouse Food Production (Agriculture Intensive)

Kenneth E Cockshull
Horticulture Research International, Warwick, UK

The best growers of crops in heated greenhouses in northern Europe can produce annual marketable yields of over 600 tons hectare (ha)$^{-1}$ of fresh tomatoes. These extraordinarily high levels of productivity make greenhouse food production one of the most intensive systems in the world. However, these crops are not eaten for either their energy or their protein contents, as water comprises more than 90% of their edible portions. In addition, there is an environmental penalty associated with their production for some 25 TJ (7 million kW h) are required to heat 1 ha of tomato-producing greenhouses for one year in England (Anon, 1999a) and that energy is usually generated from a non-renewable energy source. Furthermore, many of these salad crops could be produced in unheated glasshouses or in the eld without consuming any fuel, but then their season of production in northern Europe would be considerably shorter because of low air temperatures. Producing them in warmer regions could extend their period of availability, as at present, although there is an energy cost associated with transporting the produce to the north.

At present, there is a strong and continuing demand for greenhouse-grown edible products and there are many reasons for this. Most of the products are highly perishable, and freshness is generally perceived as a very desirable quality of such products. In addition, their texture, avor, aroma, taste, color and appearance may contribute to their appeal and some are promoted as possessing health-giving properties because they contain particular vitamins or other compounds, e.g., lycopene, a powerful antioxidant found in tomato (Giovannucci, 1999). A further positive feature for many consumers is that growers in northern Europe and North America can usually give assurances that greenhouse food crops have been produced without the application of any pesticides. Crops grown in modern greenhouses are not now raised in contact with the soil but in water enriched with the correct balance of mineral nutrients (hydroponics) and this too proves to be a good selling feature in North America, though not yet in Europe. Finally, many customers note the absence of surface blemishes on greenhouse-grown products.

The impact of global environmental change on greenhouse food production is unlikely to be very great, at least initially. The principal components of the anticipated environmental change are an increase in the carbon dioxide (CO_2) concentration of the atmosphere accompanied by an increase in average air temperature. Moderate increases in both components are likely to be bene cial for greenhouse production in northern regions. Less fuel will have to be burnt to maintain a given air temperature in heated greenhouses and a higher CO_2 concentration will enable crops to produce higher yields. Provided that the increase in temperature occurs gradually, the greenhouse growers of northern Europe should have time to adapt their patterns of cultivation. Most likely, they will simply adopt the practices already in use in southern Europe and other regions with higher average air temperatures. One indirect effect of environmental change might be that temperatures become too high to sustain crop production for many months of the year and so producers in southern regions would become less competitive. Any reduction in rainfall, however, would have a detrimental effect on all greenhouse growers as it would make irrigation water less available while increasing its cost and even, perhaps, its salt content. Present cultivation systems in greenhouses require a constant supply of water, as they are largely hydroponic, and the salinity of the irrigation water must be kept low otherwise it reduces the yield and quality of the marketable product (Cockshull, 1998).

The primary purpose of a greenhouse is to protect plants from wind and from low air and soil temperatures. However, as green plants need light to survive and to grow, at least part of the greenhouse surface must also be transparent to solar radiation. All the objects within the greenhouse absorb the radiant energy that enters and so their temperature rises but, as the greenhouse shields them from air movement, the resulting increase is much greater than in the field. Energy is slowly lost through the cladding of a

greenhouse by conduction and radiation to the surrounding air. One of the best cladding materials for greenhouses is glass, not only because it is transparent to light and impervious to rain, hail, and snow, but also because it is opaque to long-wave, infra-red radiation. Such radiation, with wavelengths longer than 2.5 μm, is radiated from the warm objects within a greenhouse. The glass cladding then absorbs this radiant energy and, because it cannot escape, the temperature of the air and of the plants within the greenhouse is sustained (Bot and van de Braak, 1995).

Most plants grow and develop to maturity faster when either the soil or the air temperature is raised within the range from 0 25 °C, and so crops can be grown to maturity earlier in a greenhouse than in the field. However, the advances in maturity are not substantial if only solar energy is used to heat the greenhouse because energy is then provided only by day. Furthermore, there is a risk that the crops will die if air temperatures are allowed to fall below 0 °C. These limitations can be overcome by burning a fuel to provide additional energy when required. The most commonly used fuels are non-renewable energy sources, such as kerosene, oil, coal, and natural gas and they are burnt either in hot-air heaters or in a boiler to produce either hot water or steam (van de Braak, 1995).

Plants grow by fixing carbon dioxide (CO_2) from the atmosphere into carbohydrates using radiant energy in the 400 700 nm waveband. The process is called photosynthesis and the waveband is called photosynthetically-active radiation (PAR) (*see* PAR (Photosynthetically Active Radiation), Volume 2). This waveband accounts for about one-half of the radiant energy reaching the earth s surface from the sun. The rate of photosynthesis and, thus, the rate of crop growth is largely determined by the amount of PAR that is absorbed by green leaves (Monteith, 1977). As CO_2 is also required for photosynthesis, the gas is added to the greenhouse atmosphere, either from tanks of the pure liquefied gas or from the combustion of a hydrocarbon fuel. For maximum productivity, the CO_2 concentration should be controlled at about 1000 parts per million volume by (vpm), air temperatures should be kept near the optimum for growth, the greenhouse should transmit as much PAR as possible and as much as possible of the transmitted PAR should be absorbed by the crop s leaves. With tomatoes, fruit yield is directly related to the amount of solar radiation transmitted by the greenhouse (Cockshull *et al.*, 1992) and so it is very important that the external surface of a greenhouse be kept clean. In the quest for maximal light transmission, glass panes as large as 2•0 • 1•25 m are supported on thin extruded aluminum glazing bars that combine strength with lightness and so require relatively little additional structural support. The outcome is that greenhouses with a single glass roof covering up to 10 hectare (ha) (Figure 1), and transmitting 70% of the solar radiation incident upon them, can be constructed (Waaijenberg, 1995).

Figure 1 The greenhouse at Runcton, England, that was built by Dalsem Horticultural Projects B.V. for Van Heyningen Bros. The new greenhouse covers more than 9 ha. (Reproduced by permission of Van Heyningen Bros)

In the south of Europe, film plastic is often the preferred cladding material and in the USA, roofs of inflated, double polythene film are preferred for their simplicity, low cost, high light transmission and high thermal resistance (Ball, 1991; Khosla, 1998).

Within the greenhouse, the transmitted PAR should be absorbed by those leaves nearing full expansion, as they are the most photosynthetically efficient. To maximize absorption, it is best to orient the crop rows east to west as then the incoming solar radiation normally has to pass through foliage and it is only in the early morning and late evening that some reaches the ground without doing so. Yield of tomatoes also increases if the crop density is increased during the first half of the year, in line with the seasonal increases in the amount of solar radiation incident upon the crop (Cockshull and Ho, 1995), presumably because the absorption of solar radiation is increased.

The temperature lift produced by solar radiation can be so great in summer that the resulting air and plant temperatures become supra optimal for crop growth. Furthermore, the water vapor pressure deficit in the greenhouse atmosphere may become so large in summer that plants close their stomata in order not to lose water too rapidly but nevertheless they may wilt. These problems can be lessened in various ways. In Europe, motorized ventilators are installed along the ridge of the roof and are opened when the temperature within the greenhouse becomes too high. In North America, cool air is drawn into greenhouses by electric fans mounted in the greenhouse walls, and drawing the air over a wet pad can further enhance the cooling effect. Alternatively, much of the radiant energy can be stopped from entering the greenhouse by shading the outside of the southern side of greenhouse roofs in summer. Growers also frequently draw a shade over the crop. This is less effective but has the advantage that the shade can readily be

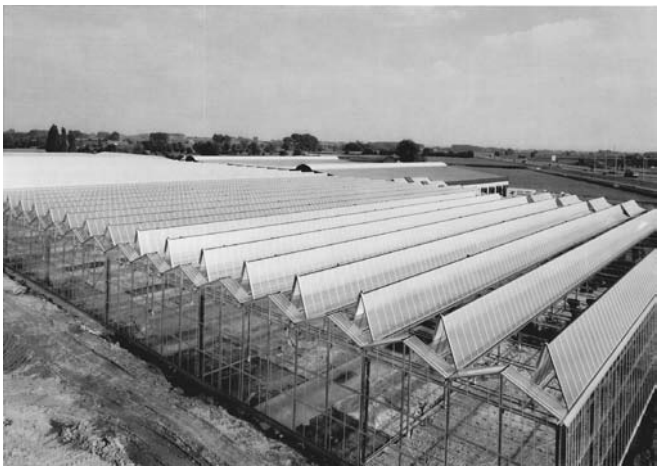

Figure 2 The Cabrio open-roof greenhouse designed by Deforche N.V

withdrawn again. Both of the last two solutions also reduce the amount of PAR that reaches the crop and so will probably reduce yield. One very practical solution is to stop growing crops in greenhouses in the hottest months and restrict their growing season to the cooler months. Other solutions are to design and construct greenhouses in which most of the roof can either be opened or be removed in summer (Figure 2). Film plastics might also be suitably modified by incorporating compounds that transmit less radiant energy in the infra-red waveband without greatly influencing the amount of PAR entering the greenhouse (e.g., Pearson and Wheldon, 1998).

The concept of forcing plants into early maturity appears to have been known since Roman times (Woods and Warren, 1988), but permanent, heated structures for protecting plants were not used in Europe until the 17th century. At that time, it was too expensive to glaze other than small areas of the walls but nevertheless, oranges could be grown in cool climates. By the middle of the 19th century, technology had advanced sufficiently to enable greenhouses to be built with glass roofs and it was then possible to produce pineapple, banana, grapes and other fruits in them. These fruits were produced only for the owner s table and it was not until the end of the 19th century that greenhouses were used to produce food for sale.

Today, the main food crops grown in greenhouses are salad crops, which are of high value (Table 1). Marketable tomato fruit are produced in heated greenhouses from the end of February until the end of October in northern Europe. The crop is usually grown at a daily average temperature in the region of 18 °C in England. This means that about 25 TJ (7 million kW h) of energy must be provided from non-renewable energy sources per hectare of modern greenhouses per year. This represents the combustion of 505 000 liters of heavy fuel oil per hectare. In addition, about 35 TJ of solar radiation are incident per hectare

Table 1 Data from Anon (1999b), © Crown copyright. (Reproduced by permission of the Controller of HMSO)

Greenhouse food crops in the UK in 1998	Planted area (ha)	Yield (tons ha$^{\bullet 1}$)	Value (£ ton$^{\bullet 1}$)
Tomato	263	407	607
Cucumber	183	459	459
Lettuce	596	35	1150
Celery	71	73	865
Sweet pepper	39	181	1006

in an average growing season, i.e., more than the energy input from fuel. With this combined energy input, the best growers can produce over 600 tons of marketable fruit per year (Anon, 1999a) although the average productivity in heated greenhouses in the UK is about 410 tons ha$^{\bullet 1}$ (Anon, 1999b). As the dry matter content of ripe tomatoes is normally less than 6% and its energy content is no more than 75 kJ 100 kg$^{\bullet 1}$, tomato is evidently not a staple foodstuff.

At present, with the exception of lettuce, it is uneconomic to grow these salad crops year-round in greenhouses in northern Europe. However, there is a year-round demand, and the demand in winter is met largely by growers in southern Europe who use both heated and unheated glass and film plastic greenhouses to produce salad crops for export. The heating requirement in the south is much less because of the higher ambient air temperatures. In southern Europe, for example, annual yields from tomatoes grown in heated greenhouses can be as great as those in northern Europe but the energy required is less than 15 TJ ha$^{\bullet 1}$. Energy is then required to transport the produce to the north but the energy cost of transporting 600 tonnes of tomatoes from southern Europe to England by lorry is estimated to be no more than 1.6 TJ. Consequently, producing tomatoes in the south and marketing them in the north requires only 60% of the non-renewable energy cost of producing them in England.

In North America and northern Europe, greenhouse-grown food crops are no longer generally grown in soil but in hydroponic systems using water enriched with appropriate nutrients (Jensen, 1998; Khosla, 1998). This nutrient-enriched water may either be continually recirculated down shallow gulleys containing the plants or it may be applied to inert, rockwool slabs in which the young plants have been established. Computers can now control the composition of the nutrient solution, the frequency of its application and its temperature. Indeed, sophisticated computer programs can now control most aspects of the root and aerial environments in which greenhouse crops are produced, including the CO_2 concentration of the atmosphere. The main advantage is that the grower then has greater control over the growth and development of the crop.

Growers in northern Europe and North America also have a considerable measure of control over the pests and diseases that could infest or infect the crop. Pests are controlled by the introduction of their natural parasites and predators, bred for this purpose by specialist companies. In North America, where fan ventilation is widely used, small insects can also be stopped from entering the greenhouse by fitting filters to the air inlets. As a result, most northern growers can give assurances that no synthetic chemicals have been used to control either pests or diseases during the course of crop production.

In respect of future global environmental change, any increase in the average concentration of CO_2 in the atmosphere will benefit the producers of greenhouse crops, as they will have to provide less CO_2 from other sources. Also, provided that increases in average air temperature continue to occur gradually and the average temperature rise does not exceed 2 °C by AD 2050 in England (Hulme and Jenkins, 1998), northern growers will require less fuel for heating greenhouses. If it does become necessary to change their present patterns of cultivation, they will presumably simply adopt those that are currently employed in warmer regions. A temperature rise will be less beneficial to growers in the warmer regions, as temperatures in their greenhouses may become too high for the production of conventional greenhouse crops. The most serious impact of potential global environmental change would be if it caused any reduction in the availability of water or any increase in either the cost or the salt content of irrigation water. Present cultivation systems for the production of greenhouse foods rely upon a constant supply of water and any increase in the salinity of that water will lead to a reduction in the yield and quality of greenhouse produce (Cockshull, 1998).

Growers are concerned about using non-renewable energy sources to heat greenhouses and many are already adopting measures that use energy more efficiently. One such measure is the cogeneration of electricity and heat in combined heat and power units that use energy more efficiently than in conventional boilers. Additional advantages are that growers can export most of the electricity that is generated, and the CO_2 that is produced as a by-product of combustion of the fuel can be introduced to the greenhouse atmosphere so that the crop synthesizes more carbohydrates per unit of radiant energy. The CO_2 produced in this way costs very little, although the flue gases must first be scrubbed to eliminate pollutants and then cooled before they can be added to the greenhouse.

Governments now propose taxes to penalize the use of non-renewable fuels and the emission of CO_2 to the atmosphere and such measures will have a negative impact on the greenhouse food industry. Considerable work on energy saving in greenhouses has already been done as a result of the sharp rise in energy prices that occurred in 1973. Few of the techniques that were tested then are still in use but the more successful ones could always be revived. The most successful technique was probably the deployment of a sheet of insulating material (a thermal screen or blanket) between the crop and the greenhouse cladding at night. The sheet was rolled up by day but it still reduced light transmission and so produced a corresponding loss of yield. It is not used today because the value of the lost yield now far exceeds the value of the energy that is saved. Double-glazing causes an even greater loss of light (Bailey and Hunter, 1988) and so the cost of fuel has to be very high to obtain any economic gain. Sheard (1979) suggested that greenhouses should use the reject heat from industrial processes and it is also feasible to heat greenhouses using geothermal energy or even renewable energy sources, such as wood or biomass. As yet, however, although there are examples of installations using these techniques, none has been widely adopted.

For the future, it seems likely that the present salad crops will remain popular for many years and that they will continue to be grown in heated greenhouses in northern Europe. However, the food industry is continually seeking novel crops to add to the present range. In the more distant future, functional foods may either be bred or be genetically engineered to contain higher concentrations of vitamins, natural anti-cancer compounds, and even antibiotics, as well as traditional herbal remedies. Provided the products are of high value, are safe, and gain the approval of the general public, they may become the greenhouse crops of the future.

Greening of Cities

Brad Bass
University of Toronto, Toronto, Canada

The greening of cities has been receiving increased attention in recent years, primarily due to its bene cial effect on modifying microclimates and the magnitude and spatial patterning of the urban heat island as well as reducing energy consumption, emissions and waste gases. Properly sited shade trees can directly reduce residential cooling loads by up to 30% (McPherson et al., *1989). An increased forest canopy in a city also means that some incoming solar radiation is used for evapotranspiration, while non-vegetated surfaces absorb the incoming solar radiation and reradiate it as heat. This heat arti cially raises urban temperatures, creating the urban heat island phenomenon (*see *Urban Heat Island, Volume 3). Reducing the urban heat island by 1 °C can result in decreases of 5% in the total electric load during the summer (Sailor, 1995). Even without reductions in the urban heat island, evaporative cooling has been estimated to reduce the cooling load of some buildings by 20- 30%. During the winter months, a row of trees (a shelter belt) along the wall of a building can reduce the heating load of a building (Minke and Witter, 1982).*

OTHER BENEFITS OF THE URBAN FOREST

However, in addition to reducing energy consumption, trees confer other benefits on a city. These include carbon sequestration, improved air quality, stormwater attenuation, noise reduction, provision of wildlife habitat, increased property value and aesthetics, food production and psychological well-being. For example, on average, over a 40-year period, each tree could sequester 3 tons of carbon (C). Additional tree cover could reduce urban stormwater runoff by 4 18% (Sanders, 1986), and can improve water quality as the pollutants end up being bound in the substrate of vegetation instead of being discharged into the environment.

Higher summer temperatures accelerate the formation of ozone in urban areas. Thus reducing the urban heat island through urban forestry will reduce the severity of smog episodes. In Southern California, simulation models have suggested that reducing the urban heat island by 2 4 °C would be equivalent to converting half of the motor vehicles to zero-emission electric engines (Taha *et al.*, 1997). Reductions in summer energy consumption directly due to shading or evaporative cooling, or indirectly through lowering the urban heat island intensity, would also reduce emissions of greenhouse gases and other compounds associated with the combustion of fossil fuels.

Trees are also effective in filtering gaseous pollution and particulates. Sublethal concentrations of some gases such as sulfur dioxide (SO_2), nitrogen oxide (N_2O), hydrogen fluoride (HF) and ozone (O_3) are neutralized through plant metabolism (Bernatzky, 1978, 1984) and through oxygenation (Grey and Deneke, 1978). Filtering of particulates occurs through sedimentation and active absorption by leaves, branches and stems. Diverting airflow prevents sediment transport, which facilitates the deposition of airborne particles. Particles tend to get trapped in the fine hairs on vegetation and are deposited into the soil or substrate when it rains. In Frankfurt, Germany, it was found that streets with trees have only 10 15% of the number of dust particles found on similar streets without trees (Minke and Witter, 1982).

These benefits are directly or indirectly related to the leaf area density of the urban forest, i.e., the amount of leaf area exposed per unit area of city. The leaf area increases exponentially with the volume of the tree crown, as do the benefits. In order for the crown to reach its full potential, sufficient space must be available for tree growth. In many commercial and industrial areas of the city, this space is not available due to the amount of land that is occupied by hard surfaces and buildings (Figure 1). Even areas that are characterized by low-density residential housing, where large amounts of land may only be occupied by turf grass, tree growth is restricted due to buffers needed to protect sidewalks and other infrastructure.

Figure 1 Restrictions on urban forestry in downtown Vancover, Canada

ROOFTOP GARDENS

One way to increase vegetation cover in urban areas is to use the roofs and walls of buildings (Figures 2 and 3). Rooftop gardens, or green roofs, provide many of the same benefits, and they take advantage of the unused roof space available in most urban areas. In addition, bare rooftops exacerbate the problems associated with removing vegetation from urban areas. For example, the heat from bare rooftops and walls can increase the urban heat island (Terjung and O Rourke, 1981a,b) (*see* Urban Heat Island, Volume 3). In the summer, a typical insulated, gravel-covered rooftop temperature can reach 60 °C. This represents a significant contribution to the urban heat island as well as the cooling load of a building. A rooftop garden can reduce these temperatures through evapotranspiration and insulation.

Based on comparisons of other vegetated and non-vegetated surfaces, evapotranspiration could maintain a summer rooftop temperature between 25 and 35 °C (Luvall and Holbo, 1989). On a large industrial building, evaporative cooling can reduce the cooling load by 20 25% (Abernathy, 1988). Insulation would reduce the variation around the mean temperature. The combined effect could be a reduction of indoor temperatures by 4 °C compared to a case without a green roof (Liesecke *et al.*, 1989). Depending on the actual vegetation, there may be additional reductions in temperature due to shading from the leaves.

During the winter, the rooftop garden would provide additional insulation on the roof. One typical type of rooftop garden, consisting of 20 cm of substrate and 20 40 cm of grass would provide the equivalent of 15 cm of rockwool. This is equivalent to an insulation factor of R20 (Minke and Witter, 1982).

A rooftop garden contributes to improved air quality in several ways. Reducing the urban heat island will decrease the severity of smog. Rooftop vegetation would also reduce the transport of particulate matter from roofs to other parts of the city. As with trees, rooftop vegetation can filter and absorb pollutants. A 2000 m^2 rooftop garden, consisting of unmowed grass, could remove 4000 kg of airborne dirt per year if the lower portion of the canopy was in contact with the moving air (Minke and Witter, 1982). Usually this is not the case, but even if this figure were reduced by 90%, each square meter of grass would still remove 0.2 kg of dirt per year. Broadmeadow and Freer-Smith (1996) summarized the results of several studies comparing the capacity of different plants to absorb nitrogen dioxide (NO_2), ammonia (NH_4) and ozone. Except for maple, birch and pine trees, all other plants may be grown in either a vertical or rooftop garden, including beans, sunflowers, petunias, tomatoes, oats and rye grass.

A large component of urban water resource management is devoted to managing stormwater runoff. Since large parts of the city are now impermeable, water has to be diverted through artificial systems, or it runs off over the surface. Stormwater runoff has contributed to water quantity and quality problems and during extreme precipitation events, it can lead to flooding and erosion. Stormwater can also be managed through storage, infiltration and retention. Alternatives to hard infrastructure include downspout disconnection, rain barrels, cisterns, swales adjacent to parking lots, retention ponds, artificial wetlands and living machines, and the use of porous materials for roads, driveways and parking

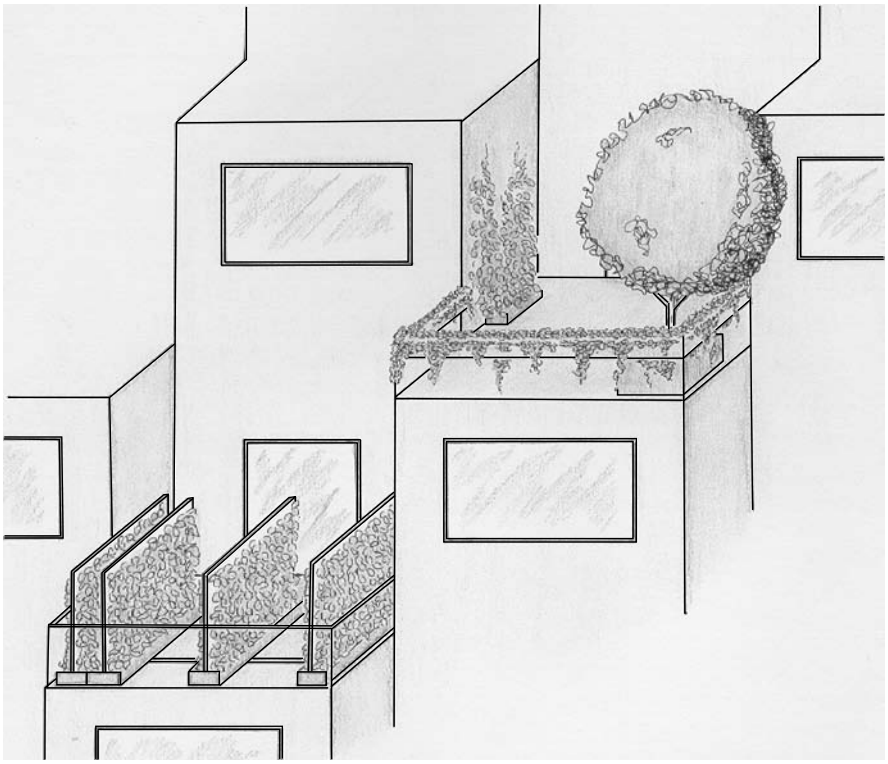

Figure 2 Rooftop garden design for high-density residential areas (J Flemming, Division of the Environment, University of Toronto)

Figure 3 Using balconies to create vertical gardens, Frieburg, Germany (A Kenney, Faculty of Forestry, University of Toronto)

lots as well as urban forestry, rooftop gardens and vertical gardens.

On a rooftop garden, nearly all rainwater from small rain showers is stored in the substrate and returned to the atmosphere by evapotranspiration. Rainwater that is not retained is released at a much slower rate and reaches storm drains after the peak flow of runoff from paved areas. In Portland, Oregon a rooftop garden with a 7 cm vegetation layer produced no runoff during a three month summer period although the retention was not as high during a continuous, heavy rainfall (Thompson, 1998). Rooftop gardens can also be used to improve water quality. Heavy metals can be bound in the substrate, as much as 95% of cadmium (Cd), copper (Cu), lead (Pb) and 16% of zinc (Zn) (Johnston and Newton, 1996). In Europe rooftop gardens (Thompson, 1998) are being designed to treat wastewater that would normally be discharged as raw sewage.

Thus even if sufficient space for trees is available, rooftop gardens would still be an important component in reducing stormwater runoff, the urban heat island and air pollution. Rooftop gardens also provide a means for recreating habitats to restore biodiversity in urban areas. Rooftop environments are similar to arid or semi-arid environments such as might be found in a prairie landscape. In the US, rooftop gardens have been used to recreate prairie habitats (North American Wetland Engineering, 1998) and in Canada, the rocky alvars of Manitoulin Island (Reid, 1998).

In Europe, there are two examples where rooftop gardens have been used as part of a wildlife corridor through the city. The first was designed for birds, insects and airborne seeds, and the second design created habitats that are analogous to islands to isolate plants whose seeds are not spread by air (Peck *et al.*, 1999). Butterflies, bees and birds have all been found in gardens above 19 stories (Johnston and Newton, 1996).

There are two basic types of rooftop gardens or green roof systems extensive and intensive. Extensive green roofs are characterized by their low weight, low capital cost and low maintenance. Typical extensive gardens consist of various grasses and wildflowers, a lightweight growing medium, a membrane to repel roots and moisture from the roof and a drainage layer to move moisture off the roof. Intensive green roofs are usually designed to resemble gardens, and may consist of various structures and a variety of plants including trees. Whereas extensive rooftop gardens are often inaccessible to the public, intensive rooftop gardens are designed to be accessible and are characterized by their increased weight, capital cost and maintenance requirements. One false preconception is that the space for rooftop gardening is limited to only flat roofs. Sloping roofs can also accommodate vegetation, and some rooftop gardens, such as hydroponic systems, may even be better suited to such roofs as gravity can be used to help circulate the water.

VERTICAL GARDENS

Walls provide an even greater amount of space for vegetation in the form of vertical gardens. Such gardens, or green walls, can comprise vines growing adjacent to a wall, window shades that utilize plants, or vertical hydroponic systems. Even in areas that are suitable for trees, they can be used to cover windows that cannot be shaded by trees due to the height or specific architectural features of a building.

Observations indicate that vertical gardens also reduce the heat flow into the building, and their surface temperature is lower than that of a bare wall, thus reducing the urban heat island. A series of experiments in Japan suggested that vines could reduce the temperature of a veranda with a southwestern exposure (Hoyano, 1988). In Germany, the vertical garden surface temperature was 10 °C cooler than a bare wall when observed at 1:30 pm in September (Wilmers, 1989). For a building in South Africa, consisting of two 10 mm fiber-cement sheets with 38 mm of fiberglass insulation, a computer simulation estimated that a vertical garden would reduce summer daytime temperatures on the surface by 5 °C (Holm, 1989).

In some cases, vertical gardens might be the preferred alternative. For example, on a multi-story building with a lot of exposure to afternoon sun during the summer, shading the windows with vertical gardens will reduce the overall cooling load significantly more than will a rooftop garden (Figure 4). However, the widespread adoption of green window shades will require additional research to devise structures to support the weight and to cope with the higher wind speeds that occur at higher elevations on multistory buildings.

CONCLUDING REMARKS

Rooftop and vertical gardens confer other benefits such as extending the life of the building envelope, spurring new economic development, and providing space for horticultural therapy and for urban agriculture. Nevertheless, neither of these technologies has been widely adopted in many countries, despite the historical precedents for doing so. Rooftop and vertical gardens can be traced back to the hanging gardens of Babylon and were known to exist in the Roman Empire, both as a response to urban population densities and to beautify institutional buildings, such as mausoleums. In Pompeii, shopkeepers grew vines on their balconies, and the ancient historian Pliny wrote about trees being imported for rooftops (Farrar, 1996). The Vikings layered the walls and roofs of their homes with turf to protect against wind and rain, and sometimes used seaweed to insulate roofs (Donnelly, 1992). During the Renaissance, steeply terraced gardens and rooftop gardens were common in the city of Genoa (Gorse, 1983).

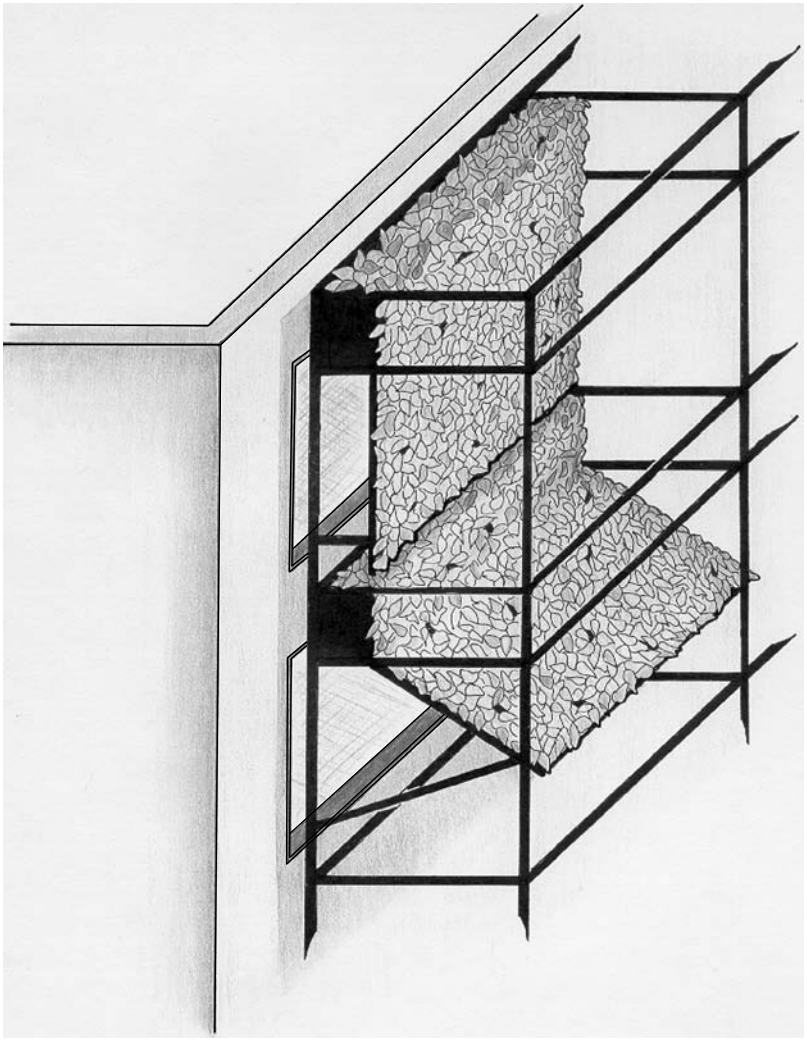

Figure 4 Vertical garden as a window shade (J Flemming, Division of the Environment, University of Toronto)

Vertical gardens in the form of hanging gardens also existed in pre-Columbian Mexico (Goode, 1986), India, and in some of the Spanish homes of 16th 17th century Mexico (Flower, 1937). In Russia, hanging gardens were favored in the 17th century Kremlin (Titova, 1990). In 18th century France, vertical gardens were constructed for the sake of aesthetics (De Lorme, 1996), and Le Corbusier and Frank Lloyd Wright, made extensive use of rooftop gardens in their designs (Curtis, 1986; Hoffman, 1995).

Recent advances in rooftop gardens have led to a technology that consists of far more than plants and soils. Proponents of rooftop gardens now advocate the use of the term *green roof infrastructure* to refer to the combination of plants, substrate, membranes and drainage layers, the latter two often being what separates one provider from another (Figures 5 and 6). Vertical gardens are still most commonly viewed as vines growing on a wall, perhaps because a clearly identified industrial sector has not yet emerged to develop and market this technology as a green

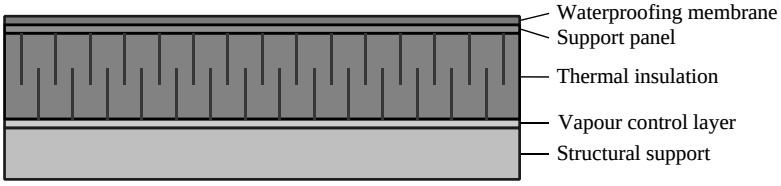

Figure 5 Conventional rooftop infrastructure (K Liu, National Research Council, Canada)

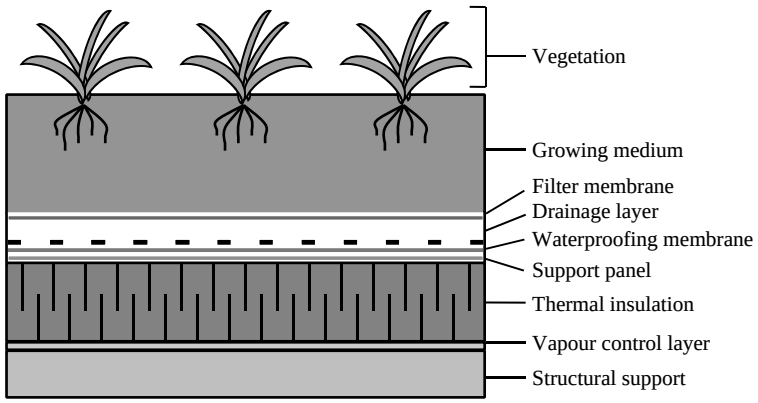

Figure 6 Green roof infrastructure (K Liu, National Research Council, Canada)

wall infrastructure. Nevertheless, green roof infrastructure and vertical gardens provide the capacity to extend the benefits of the urban forest into areas of the city where leaf area density is restricted by land use or zoning restrictions. Even where urban forestry can be expanded, it is still important to be able to mitigate the impacts of bare roofs and walls on the urban environment. By the year 2005, over 50% of the world s population will live in cities (Bindé, 1998) (*see* Urban Population Change, Volume 3). Thus, these new technologies will provide the basis to use vegetation as part of a strategy to manage the increased environmental stresses that will accompany the growing urban populations.

Groundwater Withdrawal and the Development of the Great Man-made River Project, Libya

Hedley Moorwood
Brown and Root NA Limited, Surrey, UK

In many arid and semi-arid areas, the use of groundwater has transformed the environment, either by establishing agricultural projects in desert regions or by expanding agriculture on the margins of the desert. Libya provides a good example of such transformations.

Libya has traditionally had an agricultural based economy with most of its population centered on the farming areas on and around the mountains of the Jebel Nefusa and the Jebel Akhdar at the coast. The water supply for these areas was taken from rainfall and shallow coastal aquifers. Other populated areas were centered on oases, most of which are inland.

The increasing demand for water caused by the growth of the Libyan economy could not be sustained by the minor aquifers near the coast and over-pumping led to a consequent reduction of water quality. However, the water need for the expanded coastal farming had to be met.

Exploration following the discovery of oil identi ed huge reserves of groundwater in four major interlinked basins, inland. The water slowly drains from the southern highlands through the underground rock formations of these basins to the Mediterranean, a passage that possibly takes hundreds of thousands of years. The water is replenished intermittently during periods of high rainfall. The last of these occurred in the region approximately 6500, 8000 and 9000 years ago and there is evidence that the Tibesti and Tassili mountains enjoyed wet conditions from 19 000 to 13 000 years ago when the rest of the Sahara was suffering arid conditions.

This resource was rst used to establish large agricultural schemes in the desert but these are socio-economically unattractive as they are far from population centers. Water is now being brought instead by the Great Man-made River to where it is needed along the fertile coastal strip with its existing infrastructure. This massive project is designed to bring water from large well elds in the desert to supply towns and agricultural projects along the whole coastal strip of Libya. An eventual 6.5 million cubic meters of water per day will be supplied through thousands of kilometers of pipe of up to 4.0 m in diameter. The major coastal cities of Libya are already bene ting from potable water supplied from the desert by the Project which has been under construction since the mid 1980s.

WATER USE AND RESOURCES

Libya has had a thriving coastal agriculture for thousands of years centered on the areas of the Jebel Nefusa and the Jeffara Plain in the west and the Jebel Akhdar in the east. (The Jebels are upland areas or mountains.) The main centers of population (see Figure 1) are found in these two areas with a third being situated some 700 kilometers (km) south of the Jebel Nefusa in the numerous oasis towns grouped around Wadi Shati and Wadi Ajal. To the west and south of this are the isolated oases of Ghadames and Ghat.

In the east, the coastal plain around Benghazi to the west of Jebel Akhdar is not as large as the Jeffara Plain and generally has a limestone cap-rock surface which has to be removed before agriculture can be effective or economic. The coastal side of the Jebel Akhdar itself is extremely fertile and is the main agricultural zone. South of the Jebel, the individual oases of Ajdabiya, Jalu, Awjelah, Tazerbo, Rebianah, Kufra and Oweinat are strung out to the southern border with Sudan.

In the central zone, the coastal town of Sirt is the main center with the Al Jufrah oases of Hun, Waddan and Suknah about 300 km to the south. Beyond that there is virtually no habitation, the country being dominated by the basalt highlands of the Haruj Al Aswad and farther south by the Tibesti Mountains.

Except for the areas on and near Jebel Nefusa and Jebel Akhdar that receive annual rainfalls of up to about 300 and 450 mm, respectively, evaporation exceeds precipitation over the remainder of the country and desert conditions prevail.

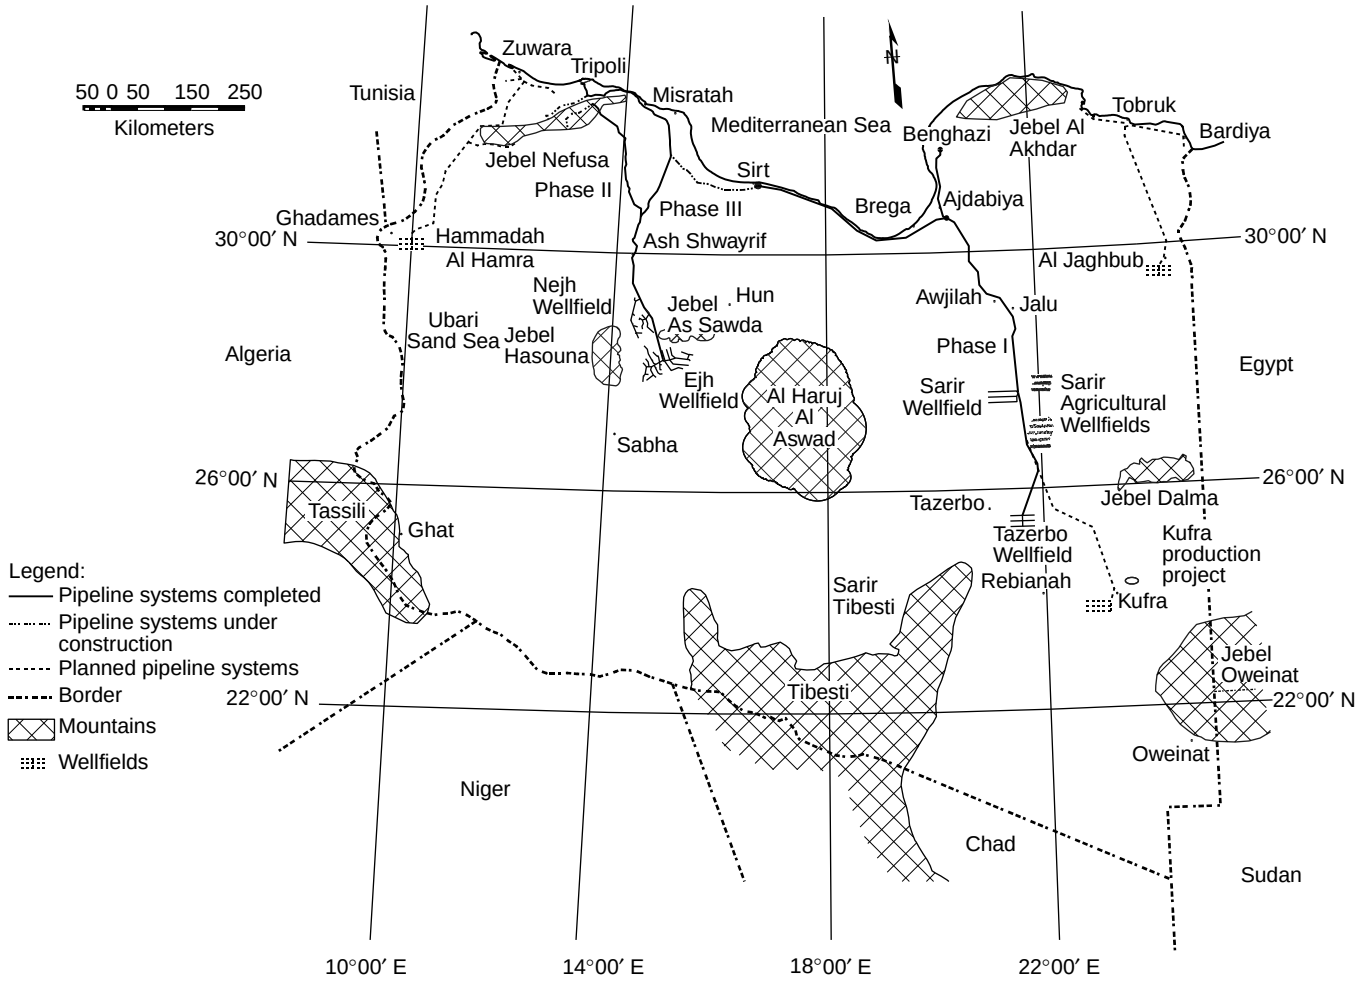

Figure 1 Location of GMRP well fields

HISTORICAL WATER USE

Traditional farming used shallow hand-dug wells, cisterns and springs for irrigation. In historical times as far back as over 2000 years ago, the agricultural area was extended inland into the system of wadis or dry river valleys cutting down through the Jebels to the coast. After heavy rain, water would flow along the wadi beds that were farmed by using trapped storm run-off caught in cisterns or dams built across the wadis (*see* Wadi, Volume 3). Extensive terracing was already developed on the hillsides of the Jebel Nefusa. In the present day, the coastal wadi systems and terracing are not farmed to the same extent, the main farming being done in large farms with better access on the plateaus of the Jebels or the plains.

Rain falls on the coastal Jebels from October to April but it tends to be in localized intense events. This results in a lot of run-off that does not provide the soil with as much recharge as it could and does not necessarily fall when or where the crops most need the rain. The use of dams and cisterns in wadis to trap the run-off sustained the level of traditional agriculture; and some indirect recharge from wadi flow into the limestone coastal aquifer helped to maintain water levels.

THE DEVELOPMENT OF AGRICULTURE AND WATER RESOURCES

In the 1960s when the oil industry was being expanded, a booming economy developed and with the continuing exploration for oil came the discovery that extensive water reserves were held in four main basins underlying Libya. The introduction of new technology and the changes in farming practice that followed resulted in the need to meet new water demands. To provide the greater quantities of irrigation and domestic water needed, pumped tube wells were used. The newly available water and Mediterranean climate at the coast enabled a full range of fruits, vegetables and cereals to be produced in ever increasing quantities for an expanding population. Dramatic environmental change

thus began in the early Seventies with major agricultural projects being established in both coastal areas and at oases to meet the aim of self-sufficiency in agricultural produce.

Oil exploration continued to prove the vast reserves of groundwater that were held inland beneath the desert. A systematic program of exploratory water well drilling began to provide details of the aquifer systems, the quality and quantity of water held in each aquifer, its nearness to the surface and rate at which it could be abstracted from the formations.

Meanwhile, in the coastal regions, the higher levels of abstraction by tubules could not be sustained by the coastal aquifers. Overpumping of the wells led to a large drawdown of the water table. Water quality deteriorated owing to saline intrusion and upcoming of lesser quality water. At the oases, expansion was limited by the unwanted effect of the increased abstraction lowering the shallow water table, which started killing off the natural, often shallow-rooted vegetation such as palm trees, and drying up lakes and springs and shallow wells. Perversely, in some oases where artesian wells were constructed, leakage caused localized flooding or oversaturation of the soil. Both of these types of situations caused marked changes to the environment of the oases concerned.

CENTER PIVOT IRRIGATION IN THE DESERT

Groundwater abstraction for the development of agriculture close to centers of population therefore had to be controlled and the Water and Soil Department within the Secretariat of Land Reclamation and Agricultural Reform, now the General Water Authority of Libya, was formed to manage the water resources. To prevent more overpumping of the coastal aquifers, the expansion of agriculture was focused on desert areas with good soil chemistry where large quantities of good quality groundwater were present. At two such locations, Kufra and Sarir (see Figure 1) center pivot irrigation schemes were started.

The first such project to pioneer large-scale desert agriculture outside the USA was built near Kufra in the late sixties, about 1000 km from the coast. The drive to use the desert for agricultural expansion led to two center pivot irrigation schemes being constructed in the mid Seventies at Sarir about 500 km south of the Jebel Akhdar. All were built in the eastern part of the country following the extensive oil and water exploration there. Kufra was an early choice because its abundance of near-surface groundwater was known. Sarir was chosen in line with the philosophy of using the desert for agriculture. The exact location was determined from mathematical modeling of the aquifer system and from water quality studies. It has a relatively high water table and flat sandy terrain and its development in its desert location far from any oases, prevented any adverse effects on existing centers.

Irrigation is provided from groundwater. Each center pivot irrigation system is centered on a well and supplied with electric power. The power operates the well pump motor and a wellhead motor that rotates a wheeled irrigation gantry from a center pivot by the wellhead. The gantry has several wheeled sections joined together to make up to the required length and the water is sprayed from it down on to the crops. The gantry slowly rotates to form an irrigated crop circle of approximately one km in diameter. The crop types grown are generally alfalfa or cereals that are suited to the irrigation system and the climate. Soil drainage and build up of salts owing to evaporation have to be monitored (*see* Salinity and Agriculture, Volume 3).

At the Kufra Production Project, the wells are spaced approximately 1.1 km apart in a matrix arranged to suit the topography of the hills to the east of Kufra. In the case of the Sarir agricultural projects, the wells are spaced every 2.5 km in double rows, 10 km apart to reduce the drawdown and spread the cone of depression of the water table. Monitoring of the water table at Kufra and Sarir has shown that the aquifers exhibit an unconfined response with the lower layers mirroring the upper layers after an initial drawdown where clay layers are present. Kufra shows a rate of drawdown at the center of the well field of 0.6 m year^{-1} over 20 years and drawdowns at the centers of the Sarir North and South agricultural well fields were recorded as less than 0.5 m year^{-1} over 7 and 11 years operation, respectively.

There are offices, accommodation buildings, workshops, storage facilities and plant and equipment at each project to run and maintain the facility and to plant, harvest and transport the crops. With the water from these wells, the desert blooms with large circles of green and the projects continue to operate although all suffer the ravages of the harsh desert environment on the equipment. There are 53 wells at the Kufra Production Project and 82 wells at the Sarir North and 157 wells at the Sarir South Agricultural Project.

The Kufra project is the most effective as it provides produce for the Kufra oases and therefore has little transportation costs and much less staffing and logistics costs as many of the staff live in Kufra. Sarir on the other hand, is situated almost 200 km from the nearest oasis and has to be manned and supported continuously. The cost of supplying the food, fuel and spares and transporting the produce hundreds of kilometers to market plus keeping a workforce operating in the desert away from their families in an inhospitable, isolated environment, makes the project much less socio-economically attractive and more difficult to run.

Although these schemes show that, with water, the desert can be used to produce crops, the area used in agricultural terms is small and the limitations of scale and their economics demanded another solution. If the coastal aquifer was already being overused and it was impractical to take agriculture to the desert where groundwater was available,

then the solution had to be that the good quality water should be piped to the fertile coastal areas. This would take advantage of existing centers of population and develop new agricultural areas away from the disadvantage of the desert environment, at the same time relieving the demand on the coastal aquifer. This solution gave rise to the Great Man-made River Project in 1982.

THE GREAT MAN-MADE RIVER PROJECT

The Great Man-made River Project is one of the largest civil engineering/water supply projects in the world today. The outline of the Project is shown on Figure 1. It carries groundwater in buried pre-cast concrete cylinder pipes, up to 4.0 m in diameter, from well fields in the desert to reservoirs and tanks and turnouts at various locations along the coast. These supply municipalities and large agricultural reservoirs. The agricultural reservoirs then provide water to new farms at each location through networks of distribution pipes. The system of agricultural reservoirs and farms is currently being expanded under the control of the Great Man-made River Water Utilization Authority.

Preliminary conceptual studies of the scheme were followed by investigations for agricultural zones, well fields and pipeline routes. To establish the water demand, potential agricultural areas were identified. Soil surveys were carried out to check soil chemistry and permeability to prevent excessive salt build-up that would harm plants and to select crops that would be tolerant of the conditions and of the water quality to be provided. These surveys and the positions of existing communities determined the end points for the system. Water demand was reviewed for each location, based on factors such as planned crop type, area to be irrigated, proposed irrigation systems and soil permeability. This planning process required the identification of water sources able to provide sufficient quantity of acceptable quality for agricultural use. Groundwater quality was also checked against municipal guidelines for potability (drinkability) because although the project was conceived as an agricultural project, the increased salinity of the coastal aquifers meant that alternative municipal supplies were also needed. The levels of chloride in the coastal aquifers were affecting taste and had accelerated corrosion in much of the water supply networks of the coastal cities, causing increased water loss and a greater maintenance burden.

The outcome of these investigations was a design to supply from desert well fields, an initial 2.0 million m^3 (i.e., metric tons) of water per day through its eastern system (Phase I) to the coastal demand areas from Sirt to Benghazi. The western system (Phase II) is to provide up to 2.5 million m^3 of water per day to the coast from Misratah to the west of Tripoli and to the Jebel Nefusa, south of Tripoli. Both Phase I and Phase II are already supplying water to the main cities and population centers along the routes of the pipelines. Phase III, which has begun, will interconnect Phases I and II and studies are underway to increase the flexibility of the system interface. A later part of Phase III will provide an additional 1.68 million m^3 of water by branching off southwards from the pipeline at Sarir and extending it into the Kufra basin where another well field will be constructed. Future Phases are in the planning stage or under design. A well field situated in the region of Ghadames in the west will pipe 0.25 million cubic meters of water per day to the coast at Zuwara. A supply to Tobruk of 0.13 million m^3 of water per day from a future well field near Al Jaghbub, approximately 300 km south of Tobruk is being designed. In the south, investigation has been underway to assess the Sarir Tibesti as a possible source from which to pipe water to Sirt.

The total cost of Phase I and Phase II is of the order of 12 billion US dollars. However, when compared to providing desalinated water in similar quantities, the unit cost of water is only 5 25% of that of desalinization, the range of cost varying with the difference in cost of the infrastructure of the relative schemes.

This vast Project already incorporates about 900 wells and well pumps, over 3000 km of 4.0 m diameter pre-cast concrete cylinder pipe, 1000 km of collector pipeline, 4000 km of haul road, a 90 mW power station, a multi-product fuel pipeline, over 4000 km of transmission and distribution power lines, 5 major pump stations, water treatment plants, flow control stations, regulating tanks and reservoirs with 35 000 000 m^3 of storage, 100 supply points, agricultural reservoirs and water distribution systems, 9 telemetry control stations interlinked with microwave radio and optical fiber networks, telecommunications and 9 operation and maintenance complexes with accommodation and office buildings for the operating body, the Great Man-made River Authority.

ENVIRONMENTAL IMPACT

The environmental impact of the project itself is limited in that the pipe and the majority of the structures are buried. The pipe has one to two meters cover and only the tops of most structures are visible because the floor level of the tanks and pump stations are built to tie in with the bottom level of the pipe, often seven meters below ground. The pipeline and structures do not therefore affect migration or movement of wild animals or of livestock and there are few settlements or crops to be disrupted as the pipeline runs mainly through desert areas.

The predicted change in piezometric head in the aquifers at the nearest towns has been checked and agreed with the General Water Authority as acceptable over the 50 year design life of the project and there are no local areas of natural vegetation where an increase in water table depth would cause problems. The monitoring of the water

table and the total abstraction from the well fields of all the projects and Municipalities in Libya allows the predictions to be refined and long-term future abstractions to be controlled and planned.

The well fields were placed well away from oases and population centers to prevent or minimize any significant interference drawdown affecting them or other existing projects. The pipeline route was studied throughout its length and any sites of known historical interest were avoided in the planning stage. Detours were made around any such sites encountered during the excavation for the pipeline. In the fertile coastal farming areas, the right of way was drastically reduced and the route planned to minimize disruption and loss of land use. Farming over the pipeline after construction and reinstatement of the ground is permitted.

Erosion protection has been introduced at cuts and wadi crossings to minimize damage from heavy rain or storm events and careful provisions made at every road and utility crossing in conjunction with all the relevant authorities and utility companies. The line is maintained by the Operating Authority which checks for erosion damage and reinstates protection where necessary. No damage or exposure of the pipe by wind erosion has been recorded.

Phase II of the Great Man-made River Project was the subject of an environmental impact study that found minimal harmful effects or potential resulting from the construction of the Project.

The results of the operation of the Project are beneficial to the population and to agriculture in the quality and quantity of water supplied. There are many other benefits following from its construction including development of the infrastructure, parallel upgrading of power and telecommunications, training and expertise and growth of Libyan companies and businesses through use of local produce and commodities.

GROUNDWATER SYSTEMS AND THE GREAT MAN-MADE RIVER PROJECT

The exploration work that followed the discovery of the huge resources of groundwater revealed the presence of

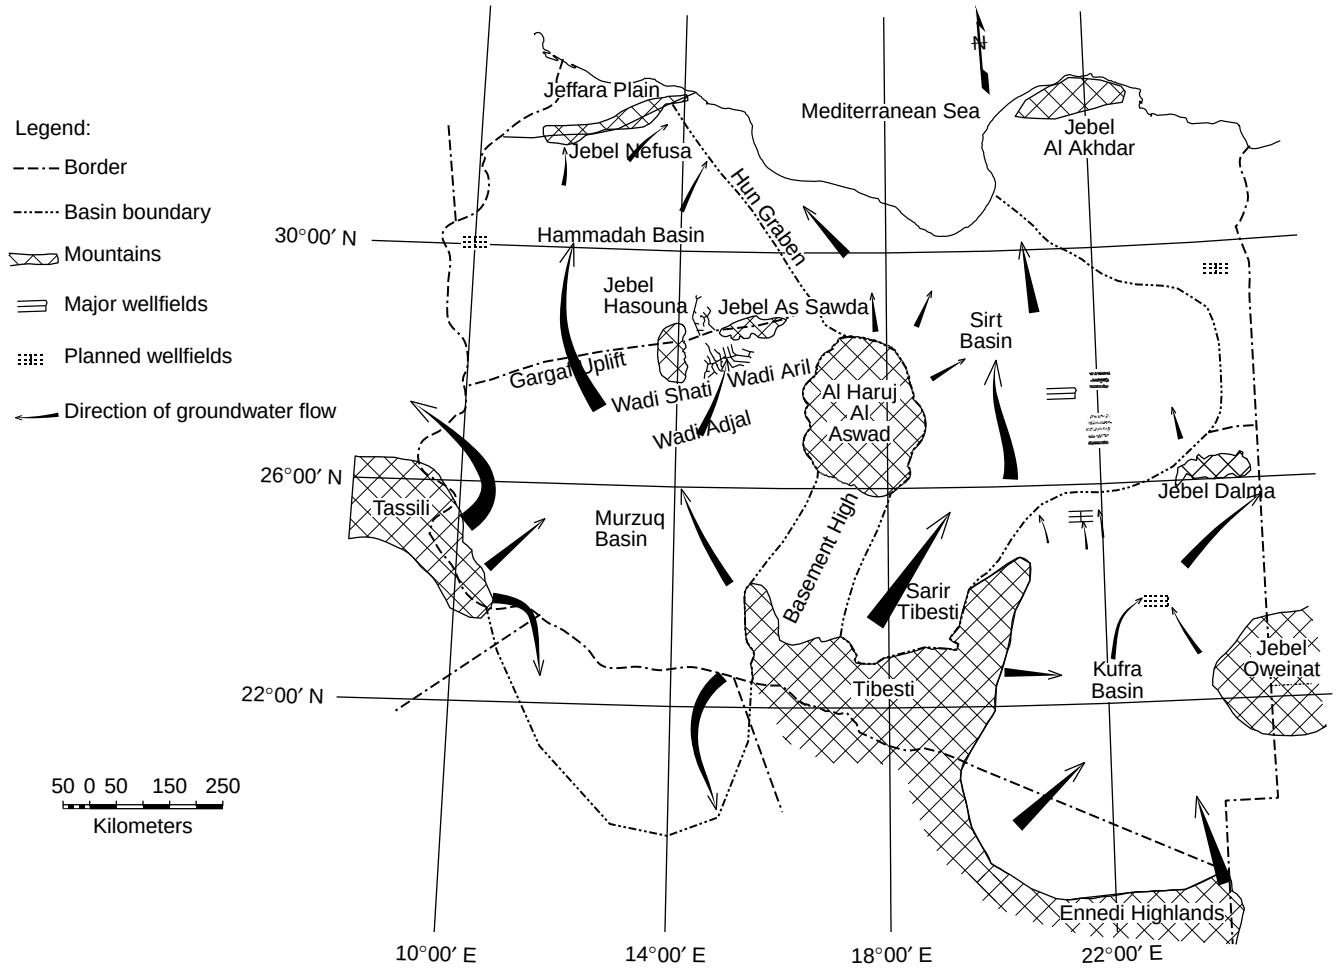

Figure 2 Groundwater flow, Libya

four main basins in Libya: the Kufra basin in the southeast, the Sirt basin in the northeast, the Murzuq basin in the southwest and the Hammadah basin in the northwest (see Figure 2). Each basin was found to contain a series of water bearing formations (aquifers) with water of different qualities depending on the origin and chemical composition of the host rocks. The aquifers are interconnected to varying extents between the basins and the whole system is considered to be draining in a quasi-steady state condition, from the southern highlands northwards to the coast. Drainage also occurs southwards from the highlands into Chad and Niger, northeastwards into Egypt from the Kufra basin and westward into Algeria from the Murzuq basin. The middle aquifer system in the Hammadah basin (the Triassic/Jurassic/Lower Cretaceous aquifer) extends as far as Morocco and is called the Continental Intercalaire.

The southern basins are continental in formation with predominantly sandstone aquifers while the northern basins suffered marine intrusions and the upper aquifers are predominantly limestone. The water quality, in terms of salinity, generally deteriorates northwards.

The ability of the aquifer system to maintain the head gradients while supporting the outflow to springs and oases, evaporation from sabkhas and other free water bodies, the water demand of the population as well as traditional agriculture and evapotranspiration losses, required that there should be a water balance for the system. With virtually no rainfall of any duration or regularity south of the coastal mountains, Jebel Nefusa and Jebel Akhdar, there is effectively zero recharge to the system. The inflow into the system is therefore considered to be provided by the depletion of the groundwater mounds in the highland areas of the Tibesti and Tassili mountains and of the southern Jebels. For the western system, this was modeled at 1.5 2.0 mm year^{-1}.

For the Great Man-made River Project, the major criteria for location of the well fields on this system were that the well fields should produce good quality water that could be economically abstracted as near to the coast as possible. Hydrogeological considerations were paramount with the cost of the pipeline length being balanced against the cost of the wells and pumping costs. The volume of water to be abstracted and the expected drawdowns precluded the use of areas with high water tables, as these were usually associated with oases where shallow wells and vegetation would be affected.

Thus the depth to the water table was not the main factor in the selection of well field locations but one of many cost factors. More important was the yield and thickness of the aquifer to sustain the abstraction and the unconfined condition to limit the spread of interference drawdowns.

The presence of old subterranean river channels was known at both Sarir and Kufra and those at Kufra were dramatically shown by the Space Shuttle radar imagery which mapped their course below the sand. This assists greatly with the understanding of the hydrogeology, especially of an upper aquifer, and the geomorphology of the area but was not available at the time of the Phase I well field design. Satellite imagery was used in Phase II to study the course of wadi drainage into the well field and was a factor used in zoning of transmissivity within the model.

PHASE I WELL FIELDS

Geological and topographical mapping together with exploratory drilling for oil and water allowed the structure of the basins to be determined and the flow system to be conceptualized. Mathematical computer models of the aquifer systems were developed in the seventies starting with the Sirt basin (Wright and Edmonds and then M. Ahmad) where the most data were available. The development of the exploratory data resulted first in the center pivot agricultural project well fields located at Sarir and then the Great Man-made River Project Phase I well fields being located at Sarir and Tazerbo. The Agricultural Projects and the Great Man-made River Project well fields at Sarir are all placed in the most northerly extent of a lobe of good quality water in the unconsolidated sediments of the upper aquifer, the Middle to Upper Miocene of the Sirt basin. The Tazerbo well field is located about 70 km from Tazerbo oasis near the northern boundary of the Kufra basin with the Sirt basin and was designed to draw water from the aquifers of the Kufra basin.

Both well fields had been modeled in the early eighties and a drawdown of the water table of about 70 90 meters in the centers of the Sarir and Tazerbo well fields was predicted after 50 years of abstraction of 1.0 million m^3 of water per day from each well field. At Sarir, 126 wells with a nominal flow rate of 92 liters s^{-1} are arranged in three rows, 10 km apart with a spacing of 1.3 km between wells. At Tazerbo, there are 108 wells with a nominal flow rate of 120 liters s^{-1} also arranged in three rows with the same spacing as at Sarir.

Owing to the closeness of the Tazerbo well field to the boundary between the basins and because of the complexity encountered there of the interconnected aquifers and the impermeable formations (*aquitards*) between them, additional modeling of the well field area was subsequently carried out by the Consultants, Brown and Root.

Exploratory wells were drilled to identify the geology and layering of the aquifers and core samples analyzed to obtain the age and permeability of the rock. The aquifers were found to be older Devonian formations rather than the Nubian deposits previously assumed. However, the geological complexity of the system and the lack of water abstraction data in the area for use in the non-steady state calibration of the model meant that it could not be used as a predictive tool as no unique solution for the calibration

could be achieved. Nevertheless, a considerable increase in the understanding of the aquifer system at the well field was achieved from the model, and the depth of some wells amended in consequence.

At Tazerbo oasis, deep wells are being drilled to provide a source of water that will not be affected in case the cone of depression from the Project s well field extends as far as the village. This removes dependency on shallow wells and provides compensatory irrigation water for shallow rooted natural vegetation that would be affected if the water table in the upper aquifer was lowered as a result. At Sarir, there are no oases or centers of population and the agricultural projects are far enough away not to be affected by the drawdown.

At both well fields, water quality analyses were carried out for the whole range of chemical and microbiological constituents to check for suitability for agricultural and potable use for corrosion potential. As the main pipeline is made of concrete, the concentration of carbon dioxide present in the waters was specifically measured because it was necessary to establish if it would result in the water dissolving the cement in the concrete pipe and weakening it. Excess free carbon dioxide can be removed from the water but removal of too much will cause deposition of calcium carbonate (scaling) on the inner surface of the pipe which will reduce the flow. Neither of these is desirable so to prevent either from occurring, the level of free carbon dioxide was established at which the waters remain neutral to the pipe. This showed that water treatment plants and upstream internal coating of the collector pipes were needed for Tazerbo well field.

PHASE II WELL FIELDS

In the west, the situation is complex. Several towns and oases exist on the northern edge of the Murzuq basin along the Wadi Shati and Wadi Ajal where the groundwater flows from the Tassili Mountains emerge. To the south of the oases, the desert surface of the Murzuq basin extends to the Tassili Mountains. To the north of the oases, the terrain is dominated by the escarpment of the Gargaf uplift and the mountains of Jebel Hasouna and Jebel As Sawda. The stony plateau of the Hammadah Al Hamra, cut by major wadis, then extends northward across the Hammadah basin to the foothills of the Jebel Nefusa with the oases of Al Jufrah to the east. To the west are the Ubari sand seas.

Several areas had previously been considered as possible locations for the well fields but none had been chosen. This and the size of the planned abstraction and the need to prevent any unacceptable interference with the numerous oases, towns or existing agricultural projects led to the decision to model the whole western aquifer system to its aquifer boundaries as had previously been done for the Al Jufrah project. By this means, the lateral continuity of the aquifers, the physical condition at those boundaries and the hydrogeological features of the original system were taken into account.

The GEASS quasi-3D finite element program developed by Pizzi and Sartori of Geomath was chosen to model the multi-layered aquifer system envisioned which was based on that postulated by Pallas with later modifications by the General Water Authority. This considers each basin to have three main aquifer layers with the lowest underlying both basins and covering almost the whole of western Libya. The middle and upper layers in each basin interconnect with each other but the main interconnection is with the underlying aquifer. The modeling, done by Geomath, was controlled by a joint committee set up under the Great Man-made River Authority with the General Water Authority, Brown and Root and their respective consultants for hydrogeological interpretation.

The water levels prior to 1970 were taken as the effective steady state condition as any traditional abstraction before that date had not caused any change in drawdown. The model was calibrated by examination and adjustment of the hydrogeological parameters to achieve close correspondence of the computed water table heads with measured values. Post 1970 abstraction and water level data were collated by the General Water Authority and used to calibrate the model in the non-steady state.

Once the model was shown to compute correctly the water table resulting from the abstractions up to 1989, it was used to test the system response to future bulk abstractions in various locations. The final well field location was chosen to tap the Cambro-Ordovician Devonian sandstone aquifer, the lowest aquifer layer that underlies both the Murzuq and the Hammadah basins. The well fields were located northeast and east of Jebel Hasouna where the Cambro-Ordovician rises up at the Gargaf uplift and outcrops and where the aquifer is therefore unconfined with only the northern edge of the well field becoming confined as the aquifer dips northwards under the Upper Cretaceous limestone. This allows the well field to utilize the specific yield of the unconfined area. The model is sensitive to regional specific yield so from the non steady state calibration, the minimum value that correctly matched the measured zero drawdown of the unconfined area up to 1989 was used.

Taking abstraction rates derived from exploratory well pump tests, it was determined that 440 production wells would be required to provide 2.0 million m^3 day^{-1} of water with piezometer wells to monitor the aquifer response. These wells are distributed over an area of 11 800 km^2 using similar spacing to those used in Phase I well fields: 1.5 km between wells in rows 10 km apart. A further seven exploratory wells were drilled to give a better spread of hydrogeological data in the area, to confirm the extent of the aquifer system in the well field area, to give more

information on drilling conditions and to confirm the water quality. Rock cores were tested for permeability and old pump test data were reworked.

The age of the water was checked and a mixed flow identified with quality varying across the area. Water quality and corrosivity studies were carried out using depth samplers, corrosivity meters, corrosion coupons and microbiological arrays. From the hydrochemistry and these data, the blend quality of the water was assessed and the water was found to be generally satisfactory for agricultural and potable use with minor treatment. As a result, carbon dioxide degassing has been introduced to remove its aggressivity to the pipeline and corrosion resistant high-grade stainless steels and fiber reinforced plastic used in the wells.

Owing to schedule constraints, large-scale mapping of this area was done by using existing aerial photography to the best scale possible. The layout of the well field was adjusted to the topography using the large scale mapping and rationalized by modeling future simulations to obtain the best response which was a maximum of about 100 meters drawdown at the center of the northeast well field after 50 years. The number of production wells was increased by 10% for standby purposes and these were added to the well field layout. The design of the well field was done by linking the results of this modeling to an hydraulics program and a costing program which defined the pipework design and the location of the structures and the connections. From this, the total pumping head at each well was calculated.

The model was also used to simulate future drawdowns that would occur on other projects and centers and to assess the future expansion scenarios to obtain 2.5 million m^3 of water day^{-1}.

The modeling exercise allowed the Phase II well field to be placed as far north as possible and away from population centers, which resulted in large cost savings and acceptable minimal interference effects and provided design criteria for much of the project. Being a regional model, it is also available for other studies and it has already been used by the General Water Authority to model the well field near Ghadames in the Triassic Jurassic Lower Cretaceous aquifer for the next Phase of the Project.

PLANNED ABSTRACTION FOR FUTURE PHASES

The Great Man-made River Project is an ongoing project that is being expanded and interlinked. The pipeline between Phase I and Phase II has been started and the studies and exploration for a model of the future well field in the Kufra basin are underway. It is intended to use a similar approach to modeling the basin and well field as that used in Phase II but the remoteness of the area means that data sources for calibration are very limited. Data collection is therefore extremely important and preliminary field trips to map the geology and gather data from existing old exploratory wells and areas of natural vegetation have been made. Aerial photography has been assembled and the existing near-surface seismic data from oil exploration reworked. A remote sensing study has already been carried out and the exploratory program for the modeling has been agreed. The model that is to be built from this will be interrogated to minimize the environmental impact of the chosen well field location.

The well field at Ghadames for the planned abstraction to supply Zuwara in the west has already been modeled and the project is being started. The results of the exploratory drilling at Al Jaghbub in the east to supply Tobruk are very encouraging. Approval for the scheme has been given and design studies are underway.

OPERATIONAL AND ENVIRONMENTAL ASPECTS

Sarir well field has been supplying water to the coastal demand areas of the Phase I system from Benghazi to Sirt since 1991 and Tazerbo well field is also completed. The northeast Jebel Hasouna well field has been producing water for Tripoli and the other Phase II locations since 1996.

Data are collected from production wells by the telemetry systems and from the piezometer wells by data recorders to monitor the performance of the well fields, the flows and drawdowns of the wells and the cones of depression against the predicted values. These are used for continual upgrading of the database of measured values and will be used for the later recalibration of the models. The telemetry is also used to zone production within the well fields to meet the demand taking into account the performance of each well. The 10% standby capacity allows for maintenance of the wells.

The environmental impact of the groundwater abstraction of the Great Man-made River Project itself is minimal owing to the remoteness of the well fields and the precautions taken. The amount of water abstracted, although large, is tiny compared to the volume available and at the planned rate of abstraction, the water mounds in the southern highlands driving the system will be recharged in geological time at the next pluvial before any significant depletion of them occurs with or without the Great Man-made River Project. The buried nature of the pipelines means that the system has little effect on the environment and the supply of the water to the coastal regions will alleviate the harmful effects of overpumping of the coastal aquifers that have already taken place and provide improved potable water quality. Although the quantity of water is large, the increase in new agricultural areas is small

in comparison to existing agriculture areas. As a result, no major environmental change is expected.

Harmful Algal Blooms (HABs)

I J Hodgkiss
The University of Hong Kong, Pokfulam Road, Hong Kong

Occasionally, many coastal areas of the world experience the rapid formation of dense, visible patches of microscopic marine plants near the surface of the water offshore. When these plants contain reddish pigments, they give a red appearance to the sea, leading to the popular description of red tides.

Harmful algae are microscopic, single-celled plants that live in the sea. The world s oceans are home to a dazzling array of small plant and animal life, which together we call *plankton*. The plants, the algae or phytoplankton, are the base of the entire marine food web, leading eventually to the largest marine mammals the whales, the largest marine fish (the whale sharks) and, of course, to humans who feed on the fruit of the seas.

When these algae grow in large numbers we call them blooms and these blooms may reveal the colors of the algal pigments red, brown, yellow, etc. The most obvious are those we call the red tides, caused by minute algae called dinoflagellates.

Sometimes these blooms can have adverse impacts on the environment, its inhabitants, and on people when those inhabitants are used as food. The impacts of these harmful algae blooms (HABs) may be due to the sheer numbers of cells clogging fish gills; or they may be due to the deoxygenation resulting from such large numbers of breathing cells; or, in a small number of cases (not more than a few dozen), they may actually produce poisonous or toxic substances.

These toxins may be accumulated in shellfish, as they filter the water for food and oxygen, until they reach levels that can harm humans or other consumers in the marine food web. Or, they may kill fish, particularly those held in pens or cages in mariculture areas. HABs are global phenomena and research studies all over the world suggest that the nature and extent of this HAB problem has been expanding over the last few decades. There are now reports from almost every coastal country. Explanations for this increase range from natural species dispersal by ocean currents, to an increase in human-related and global activities such as transport of species in ship ballast water, increased inshore activities and pollution, to more vigilance. This last reason has little validity where increases have been recorded in the past 20 years by monitoring programs that have changed little over that time.

Phytoplankton bloom dynamics are related to nutrient supply, and this might result from riverine inflows of water, containing nutrients derived from natural sources, being drained into the rivers from their surrounding catchments during rainfall, or sewage effluent inflows generated by Man, or the upwelling of nutrient rich waters from the oceans depths. This process of nutrient enrichment (*eutrophication*) can thus be natural or man-made (*see* Eutrophication, Volume 2). However, evidence is accumulating from all over the world that accelerated eutrophication, i.e., the speeding up of this natural process by people-made inputs of domestic, agricultural and industrial wastes, is stimulating algal growth in coastal waters and leading to undesirable changes. Thus, a persistent and global pattern has emerged of a long-term increased frequency of HABs associated with coastal marine pollution.

The nature of the HAB problem has changed considerably since 1975 in the US. Previously problems arose in scattered localities in a few states, but now virtually every coastal state is threatened, in many cases over large geographic areas and by more than one harmful or toxic algal species. The number of toxic blooms, the economic losses from them, the types of resources affected, and the number of toxins and toxic species have all increased markedly, not only in the US, but throughout the world. Few US coastal waters are unaffected by HABs. In the 1990s, fish kills in the middle Atlantic states were linked to a newly discovered organism called *P esteria*. Florida and other Gulf Coast states are subject to fish kills from *Gymnodinium breve* red tides. The tropical areas of the Florida Keys, Hawaii, and

Puerto Rico have experienced ciguatera fish poisoning for some time.

In southeast Asia, red tides have been observed in many coastal waters such as bays in the Philippines, Brunei Bay and off Sabah, Malaysia. The casualties due to the consumption of contaminated fisheries products have also been significant. A red tide reported in Hong Kong in late March 1998 affected about 1000 of Hong Kong s 1500 fish farms and killed two-thirds of the marine fish farm population at an estimated loss of HK$120 million. It forced the closure of the popular Repulse Bay beach. Local pollution by phosphorous in industrial sewage, probably from heavy industries like dye factories and shipbuilding plants in Guandgong province, was blamed for the algal bloom.

Climate change could alter local habitats and change the areas where ciguatera toxin is produced, but such changes might be undetected by local fishermen or regulators. Warming would expand the range for ciguatera and other biotoxins and could lead to increased biotoxin poisoning.

To most scientists, the future appears to be clear a concerted effort is necessary to protect our marine environment before the effects of waste disposal become overwhelming. In many countries this effort has begun, others have yet to recognize the problems.
